Non-Exclusive Competition in the Market for Lemons∗

First Draft: October 2007
This draft: April 2009

Abstract
We consider an exchange economy in which a seller can trade an endowment of a
divisible good whose quality she privately knows. Buyers compete by offering menus of
non-exclusive contracts, so that the seller may choose to trade with several buyers. In
this context, we show that an equilibrium always exists and that aggregate equilibrium
allocations are generically unique. We provide a fully strategic foundation for Akerlof’s
(1970) partial pooling result: in equilibrium, goods of low quality are traded at the
same price, while goods of higher quality may end up not being traded at all if the
adverse selection problem is severe. We contrast our findings with those of standard
competitive screening models that postulate enforceability of exclusive contracts, and
we discuss their implications for empirical tests of adverse selection in financial markets.

1 Introduction

Adverse selection is widely recognized as a major obstacle to the efficient functioning of markets. This is especially true on financial markets, where buyers care about the quality of the assets they purchase, and fear that sellers have superior information about it. The same difficulties impede trade on second-hand markets and insurance markets. Theory confirms that adverse selection may indeed have a dramatic impact on economic outcomes. First, all mutually beneficial trades need not take place in equilibrium. For instance, in Akerlof’s (1970) model of second-hand markets, only the lowest quality goods are traded at the equilibrium price. Second, there may be difficulties with the very existence of equilibrium. For instance, in Rothschild and Stiglitz’s (1976) model of insurance markets, an equilibrium fails to exist whenever the proportion of low-risk agents is too high.

Most contributions to the theory of competition under adverse selection have considered frameworks in which competitors are restricted to make exclusive offers. This assumption is for instance appropriate in the case of car insurance, since law forbids to take out multiple policies on a single vehicle. By contrast, competition on financial markets is typically non-exclusive, as each agent can trade with multiple partners who cannot monitor each others’ trades with the agent.\(^1\) This paper argues that this difference in the nature of competition may have a significant impact on the way adverse selection affects market outcomes. This has two important consequences, that we discuss in the conclusion. First, empirical studies that test for the presence of adverse selection should use different methods depending on whether or not competition is exclusive. Second, the regulation of markets plagued by adverse selection should be adjusted to the type of competition that prevails on them.

To illustrate these points, we consider a stylized model of trade under adverse selection. In our model, a seller endowed with some quantity of a good attempts to trade it with a finite number of buyers. The seller and the buyers have linear preferences over quantities and transfers exchanged. In line with Akerlof (1970), the quality of the good is the seller’s private information. Unlike in his model, the good is assumed to be perfectly divisible, so that any fraction of the seller’s endowment can potentially be traded. An example that fits these assumptions is that of a firm which floats a security issue by relying on the intermediation services of several investment banks. Buyers compete by simultaneously offering menus of

---

\(^1\)Examples of this phenomenon abound across industries. In the banking industry, Detragiache, Garella and Guiso (2000), using a sample of small and medium-sized Italian firms, document that multiple banking relationships are very widespread. In the credit card industry, Rysman (2007) shows that US consumers typically hold multiple credit cards from different networks, although they tend to concentrate their spending on a single network. Cawley and Philipson (1999) and Finkelstein and Poterba (2004) report similar findings for the US life insurance market and the UK annuity market.
contracts, or, equivalently, price schedules. After observing the menus offered, the seller decides of her trade(s). Competition is exclusive if the seller can trade with at most one buyer, and non-exclusive if trades with several buyers are allowed.

Under exclusive competition, our conclusions are qualitatively similar to Rothschild and Stiglitz’s (1976). In a simple version of the model with two possible levels of quality, pure strategy equilibria exist if and only if the probability that the good is of high quality is low enough. Equilibria are separating: the seller trades her whole endowment when quality is low, while she only trades part of it when quality is high.

The analysis of the non-exclusive competition game yields strikingly different results. Pure strategy equilibria always exist, both for binary and continuous quality distributions. Aggregate equilibrium allocations are generically unique, and have an all-or-nothing feature: depending on whether quality is low or high, the seller either trades her whole endowment or does not trade at all. Buyers earn zero profit on average in any equilibrium. These allocations can be supported by simple menu offers. For instance, there exists an equilibrium in which every buyer offers to buy any quantity at a given unit price. This price is equal to the expectation of the buyers’ valuation of the good conditional on the seller accepting to trade at that price. While other menu offers are consistent with equilibrium, corresponding to non-linear price schedules, an important insight of our analysis is that this price is also the unit price at which all trades take place in any equilibrium.

These results are of course in line with Akerlof’s (1970) classic analysis of the market for lemons, for which they provide a fully strategic foundation. It is worth stressing the differences between his model and ours. Akerlof (1970) considers a market for a non-divisible good of uncertain quality, in which all agents are price-takers. Thus, by assumption, all trades must take place at the same price, in the spirit of competitive equilibrium models. Equality of supply and demand determines the equilibrium price level, which is equal to the average quality of the goods that are effectively traded. Multiple equilibria may occur in a generic way. By contrast, we allow agents to trade any fraction of the seller’s endowment. Moreover, our model is one of imperfect competition, in which a fixed number of buyers choose their offers strategically. In particular, our analysis does not rely on free entry arguments. Finally, buyers can offer arbitrary menus of contracts, including for instance non-linear price schedules. That is, we avoid any a priori restrictions on instruments. The

---

2 As established by Peters (2001) and Martimort and Stole (2002), there is no need to consider more general mechanisms in this multiple-principal single-agent setting.

3 This potential multiplicity of equilibria arises because buyers are assumed to be price-takers. Mas-Colell, Whinston and Green (1995, Proposition 13.B.1) show that the equilibrium is generically unique when buyers strategically set prices for the non-divisible good offered by the seller.
fact that all trades take place at a constant unit price in equilibrium is therefore no longer an assumption, but rather a consequence of our analysis.

A key to our results is that non-exclusive competition expands the set of deviations that are available to the buyers. Indeed, each buyer can strategically use the offers of his competitors to propose additional trades to the seller. Such deviations are blocked by latent contracts, that is, contracts that are not traded in equilibrium but which the seller finds it profitable to trade at the deviation stage. These latent contracts are not necessarily complex nor exotic. For instance, in a linear price equilibrium, all the buyers offer to purchase any quantity of the good at a constant unit price, but only a finite number of contracts can end up being traded as long as the seller does not randomize on the equilibrium path. One of the purposes of the other contracts, which are not traded in equilibrium, is to deter cream-skimming deviations that aim at attracting the seller when quality is high. The use of latent contracts has been criticized on several grounds. First, they may allow one to support multiple equilibrium allocations, and even induce an indeterminacy of equilibrium. This is not the case in our model, since aggregate equilibrium allocations are generically unique. Second, a latent contract may appear as a non-credible threat, if the buyer who issues it would make losses in the hypothetical case where the seller were to trade it. Again, this need not be the case in our model. In fact, we construct examples of equilibria in which latent contracts would be strictly profitable if traded.

This paper is related to the literature on common agency between competing principals dealing with a privately informed agent. In the context of incomplete information, a number of recent contributions use standard mechanism design techniques to characterize equilibrium allocations. The basic idea is that, given a profile of mechanisms proposed by his competitors, the best response of any single principal can be fully determined by focusing on simple menu offers corresponding to direct revelation mechanisms. This allows one to construct equilibria that satisfy certain regularity conditions. This approach has been recently applied in various common agency contexts. Closest to this paper is Biais, Martimort and Rochet (2000), who study non-exclusive competition among principals in a common value environment. In their model, uninformed market-makers supply liquidity to an informed insider. The insider’s preferences are quasi-linear, and quadratic with respect to quantities exchanged. Unlike in our model, the insider has no capacity constraint. Variational techniques are

\[\text{\textsuperscript{4}}\text{In a complete information setting, Martimort and Stole (2003) show that latent contracts can be used to support any level of trade between the perfectly competitive outcome and the Cournot outcome.}\]

\[\text{\textsuperscript{5}}\text{Latent contracts with negative virtual profits have been for example considered in Hellwig (1983).}\]

used to construct an equilibrium in which market-makers post convex price schedules. Such
techniques do not apply in our model, as all agents have linear preferences and the seller
cannot trade more than her endowment. Instead, we allow for arbitrary menu offers, and we
characterize candidate equilibrium allocations in the usual way, that is, by checking whether
they survive possible deviations. While this approach may be difficult to apply in more
complex settings, it delivers several interesting new insights, in particular on the role of
latent contracts.

The paper is organized as follows. Section 2 introduces the model. Section 3 focuses on
a two-type setting. We show that there always exists a market equilibrium where buyers
play a pure strategy. In addition, equilibrium allocations are generically unique. We also
characterize equilibrium menu offers, with special emphasis on latent contracts. Section 4
analyzes the general framework with a continuum of sellers’ types. Section 5 concludes.

2 The Model

2.1 Non-Exclusive Trading under Asymmetric Information

There are two kinds of agents: a single seller, and a finite number of buyers indexed by
$i = 1, \ldots, n$, where $n \geq 2$. The seller has an endowment consisting of one unit of a perfectly
divisible good that she can trade with one or several buyers. Let $q^i$ be the quantity of the
good purchased by buyer $i$, and $t^i$ the transfer he makes in return. Feasible trade vectors
$((q^1, t^1), \ldots, (q^n, t^n))$ are such that $q^i \geq 0$ and $t^i \geq 0$ for all $i$, with $\sum_i q^i \leq 1$. Thus the
quantity of the good purchased by each buyer must be at least zero, and the sum of these
quantities cannot exceed the seller’s endowment.

Our specification of the agents’ preferences follows Samuelson (1984). The seller has
preferences represented by

$$ T - \theta Q, $$

where $Q = \sum_i q^i$ and $T = \sum_i t^i$ denote aggregate quantities and transfers. Here $\theta$ is a
random variable that stands for the quality of the good as perceived by the seller. Each
buyer $i$ has preferences represented by

$$ v(\theta)q^i - t^i. $$

Here $v(\theta)$ is a deterministic function of $\theta$ that stands for the quality of the good as perceived
by the buyers. Observe that there are no externalities across buyers beyond the fact that
the quantities they trade cannot in the aggregate exceed the seller’s endowment.
We will typically assume that \( v(\theta) \) is not a constant function of \( \theta \), so that both the seller and the buyers care about \( \theta \). Gains from trade arise in this common value environment if \( v(\theta) > \theta \) for some realization of \( \theta \). However, in line with Akerlof (1970), mutually beneficial trades are potentially impeded because the seller is privately informed of the quality of the good at the trading stage. Following standard terminology, we shall hereafter refer to \( \theta \) as to the type of the seller.

Trading is non-exclusive in the sense that no buyer can contract on the trades that the seller makes with his competitors.\(^7\) Thus, as in Biais, Martimort and Rochet (2000) or Segal and Whinston (2003), a contract describes a bilateral trade between the seller and a particular buyer; a menu is a set of such contracts. Buyers compete in menus for the good offered by the seller. The seller can simultaneously trade with several buyers, and optimally combine the offers made to her, subject to her endowment constraint. The following timing of events characterizes our non-exclusive competition game:

1. Each buyer \( i \) proposes a menu of contracts, that is, a set \( C^i \) of quantity-transfer pairs \( (q^i, t^i) \in [0, 1] \times \mathbb{R}_+ \) that contains at least the no-trade contract \((0, 0)\).\(^8\)

2. After privately learning the quality \( \theta \), the seller selects one contract \((q^i, t^i)\) from each of the menus \( C^i \)'s offered by the buyers, subject to the constraint that \( \sum_i q^i \leq 1 \).

A pure strategy for the seller is a function that maps each type \( \theta \) and each menu profile \((C^1, \ldots, C^n)\) into a vector of contracts \((q^1, t^1), \ldots, (q^n, t^n)\) \(\in ([0, 1] \times \mathbb{R}_+)^n\) such that \((q^i, t^i) \in C^i\) for all \( i \) and \( \sum_i q^i \leq 1 \). To ensure that the seller’s problem

\[
\sup \left\{ \sum_i t^i - \theta \sum_i q^i : (q^i, t^i) \in C^i \text{ for all } i \text{ and } \sum_i q^i \leq 1 \right\}
\]

has a solution for any type \( \theta \) and menu profile \((C^1, \ldots, C^n)\), we require the buyers’ menus to be compact sets. Throughout the paper, and unless stated otherwise, the equilibrium concept is pure strategy perfect Bayesian equilibrium.

### 2.2 Applications

Our model is basically a model of trade, with the following features: the good is divisible; its quality is the seller’s private information; and the seller may trade with several buyers.

\(^7\)In particular, buyers cannot make transfers contingent on the whole profile of quantities \((q^1, \ldots, q^n)\) traded by the seller. This distinguishes our trading environment from a menu auction à la Bernheim and Whinston (1986a).

\(^8\)As usual, the assumption that each menu must contain the no-trade contract allows one to deal with participation in a simple way.
As such it can be applied to many markets. The following examples illustrate some possible applications.

**Financial Markets** In line with DeMarzo and Duffie (1999) or Biais and Mariotti (2005), one can think of the seller as an issuer attempting to raise cash by selling a security backed by some of her assets, and of the buyers as underwriters managing the issue. Under risk-neutrality, gains from trade arise in this context if the issuer discounts future cash-flows at a higher rate than the market; this may for instance reflect credit constraints or, in the financial services industry, binding minimum-capital requirements. The marginal cost of the security for the issuer, that is, its value to the issuer if retained, is then only a fraction of the value of the security to the underwriters: formally, one has $\theta = \delta v(\theta)$ for some constant $\delta \in (0, 1)$. Here $Q$ is the total fraction of the security sold by the issuer, while $1 - Q$ is the residual fraction of the security that the issuer retains. It is natural to assume that, at the issuing stage, the issuer has better information than the underwriters about the value of her assets, and hence about the value of the security she issues.

**Labor Market** In an alternative interpretation of the model, the seller is a worker, and the buyers are firms. The worker can work for several firms, and divide her time endowment accordingly. This is for instance the case in legal or financial services, where a consultant typically works on behalf of several customers; similarly, a salesman can represent different companies. The worker’s type $\theta$ is her opportunity cost of selling one unit of her time to any given firm, while $v(\theta)$ is the productivity of a worker of type $\theta$. Here $Q$ is the total fraction of time spent working, while $1 - Q$ is the residual fraction of time that the worker can spend on leisure. This interpretation differs from the labor market model of Mas-Colell, Whinston and Green (1995, Chapter 13, Section B) in that labor is assumed to be divisible, and competition for the worker’s services is non-exclusive.

**Insurance Markets** A final interpretation of our setup is as a model of insurance provision, where the insured’s preference are modeled using Yaari’s (1987) dual theory of choice under risk, so that her utility is linear in wealth but non linear in probabilities. Here the roles of the seller and of the buyers are reversed. There is a single insured, who can purchase insurance from several insurance companies. The insured has wealth $W$, and can incur a loss $L$ with privately known probability $x$. An insurance contract consists of a reimbursement $r^i$ and of a premium $p^i$. The utility that the insured derives from aggregate reimbursements $R = \sum_i r^i$ and aggregate premia $P = \sum_i p^i$ is

$$W - P - f(x)(L - R),$$
while the profit of insurance company $i$ is

$$p^i - x r^i.$$

One assumes that overinsurance is prohibited, so that $R$ is at most equal to $L$. Letting $t^i = -p^i$, $q^i = r^i$, $\theta = -f(x)$ and $v(\theta) = -x$ leads back to our model. Gains from trade arise in this context if some type of the issuer puts more weight on the occurrence of a loss than the insurance company does, that is, if $f(x) > x$ for some realization of $x$.

3 The Two-Type Case

In this section, we consider the binary version of our model in which the seller’s type can be either low, $\theta = \underline{\theta}$, or high, $\theta = \overline{\theta}$, for some $\overline{\theta} > \theta > 0$. Denote by $\nu \in (0, 1)$ the probability that $\theta = \overline{\theta}$ and by $E$ the corresponding expectation operator. In order to focus on the most interesting case, we assume that the seller’s and the buyers’ perceptions of the quality of the good move together, that is, $v(\overline{\theta}) > v(\theta)$, and that it would be efficient to trade no matter the quality of the good, that is, $v(\theta) > \underline{\theta}$ and $v(\overline{\theta}) > \overline{\theta}$.

3.1 The Exclusive Competition Benchmark

As a benchmark, it is helpful to characterize the equilibrium outcomes under exclusive competition, that is, when the seller can trade with at most one buyer, as in standard models of competition under adverse selection. The timing of the exclusive competition game is similar to that of the non-exclusive competition game, except that the second stage is replaced by

2’. After privately learning the quality $\theta$, the seller selects one contract $(q^i, t^i)$ from one of the menus $C^i$’s offered by the buyers.

Given a menu profile $(C^1, \ldots, C^n)$, the seller’s problem then becomes

$$\sup \{t^i - \theta q^i : (q^i, t^i) \in C^i \text{ for some } i\}.$$  

Let $(q_e, t_e)$ and $(\overline{q}, \overline{t})$ be the contracts traded by each type of the seller in an equilibrium of the exclusive competition game. One has the following result.

Proposition 1 The following holds:

(i) Any equilibrium of the exclusive competition game is separating, with

$$(q_e, t_e) = (1, v(\theta)) \text{ and } (\overline{q}, \overline{t}) = \frac{v(\theta) - \theta}{v(\theta) - \underline{\theta}} (1, v(\theta)).$$
(ii) The exclusive competition game has an equilibrium if and only if \( \nu \leq \nu^e \), where

\[
\nu^e = \frac{\bar{\theta} - \theta}{v(\bar{\theta}) - \bar{\theta}}.
\]

Hence, when the rules of the competition game are such that the seller can trade with at most one buyer, the structure of market equilibria is formally analogous to that obtaining in the competitive insurance model of Rothschild and Stiglitz (1976). First, any pure strategy equilibrium is separating, with type \( \theta \) selling her whole endowment, \( q^e = 1 \), and type \( \bar{\theta} \) only selling a fraction of her endowment, \( 0 < \bar{q}^e < 1 \). The corresponding contracts are traded at unit prices \( v(\theta) \) and \( v(\bar{\theta}) \) respectively, yielding each buyer a zero payoff. Second, type \( \theta \) is indifferent between her equilibrium contract and that of type \( \bar{\theta} \), implying

\[
\bar{q}^e = \frac{v(\theta) - \theta}{v(\bar{\theta}) - \bar{\theta}}
\]

as stated in Proposition 1(i). The equilibrium is depicted on Figure 1. Point \( A^e \) corresponds to the equilibrium contract of type \( \theta \), while point \( \bar{A}^e \) corresponds to the equilibrium contract of type \( \bar{\theta} \). The two solid lines passing through these points are the equilibrium indifference curves of type \( \theta \) and type \( \bar{\theta} \). The dotted line passing through the origin are indifference curves for the buyers, with slopes \( v(\theta) \) and \( v(\bar{\theta}) \).

---Insert Figure 1 here---

As in Rothschild and Stiglitz (1976), a pure strategy equilibrium exists under exclusivity only under certain parameter restrictions. Specifically, the equilibrium indifference curve of type \( \bar{\theta} \) must lie above the indifference curve for the buyers with slope \( E[v(\theta)] \) passing through the origin, for otherwise there would exist a profitable deviation attracting both types of the seller. As stated in Proposition 1(ii), this is the case if and only if the probability \( \nu \) that the good is of high quality is low enough.

### 3.2 Equilibrium Outcomes under Non-Exclusive Competition

We now turn to the analysis of the non-exclusive competition model. We first characterize the restrictions that equilibrium behavior implies for the outcomes of the non-exclusive competition game. Next, we show that this game always has an equilibrium in which buyers post linear prices. Finally, we contrast the equilibrium outcomes with those arising in the exclusive competition model.
3.2.1 Aggregate Equilibrium Allocations

Let $c_i = (q_i, t_i)$ and $c\bar{i} = (\bar{q}_i, \bar{t}_i)$ be the contracts traded by the two types of the seller with buyer $i$ in equilibrium, and let $(Q, T) = \sum_i c_i$ and $(\bar{Q}, \bar{T}) = \sum_i c\bar{i}$ be the corresponding aggregate equilibrium allocations. To characterize these allocations, one only needs to require that three types of deviations by a buyer be blocked in equilibrium. In each case, the deviating buyer uses the offers of his competitors as a support for his own deviation. This intuitively amounts to pivoting around the aggregate equilibrium allocation points $(Q, T)$ and $(\bar{Q}, \bar{T})$ in the $(Q, T)$ space. We now consider each deviation in turn.

**Attracting Type $\theta$ by Pivoting Around $(Q, T)$**  The first type of deviations allows one to prove that type $\theta$ always trades efficiently in equilibrium.

**Lemma 1** \( Q = 1 \) in any equilibrium.

One can illustrate the deviation used in Lemma 1 as follows. Observe first that a basic implication of incentive compatibility is that, in any equilibrium, $Q$ cannot be higher than $\bar{Q}$. Suppose then that $Q < 1$ in a candidate equilibrium. This situation is depicted on Figure 2. Point $A$ corresponds to the aggregate equilibrium allocation $(Q, T)$ traded by type $\theta$, while point $A'$ corresponds to the aggregate equilibrium allocation $(\bar{Q}, \bar{T})$ traded by type $\bar{\theta}$. The two solid lines passing through these points are the equilibrium indifference curves of type $\theta$ and type $\bar{\theta}$, with slopes $\theta$ and $\bar{\theta}$. The dotted line passing through $A$ is an indifference curve for the buyers, with slope $v(\theta)$.

--- Insert Figure 2 here ---

Suppose now that some buyer deviates and includes in his menu an additional contract that makes available the further trade $AA'$. This leaves type $\bar{\theta}$ indifferent, since she obtains the same payoff as in equilibrium. Type $\bar{\theta}$, by contrast, cannot gain by trading this new contract. Assuming that the deviating buyer can break the indifference of type $\theta$ in his favor, he strictly gains from trading the new contract with type $\theta$, as the slope $\theta$ of the line segment $AA'$ is strictly less than $v(\theta)$. This contradiction shows that one must have $Q = 1$ in equilibrium. The assumption on indifference breaking is relaxed in the proof of Lemma 1.

**Attracting Type $\bar{\theta}$ by Pivoting Around $(\bar{Q}, \bar{T})$** Having established that $Q = 1$, we now investigate the aggregate quantity $\bar{Q}$ traded by type $\bar{\theta}$ in equilibrium. The second type of deviations allows one to partially characterize the circumstances in which the two types of the seller trade different aggregate allocations in equilibrium. We say in this case that
the equilibrium is *separating*. An immediate implication of Lemma 1 is that $Q < 1$ in any separating equilibrium. Let then $p = \frac{T - T}{1 - Q}$ be the slope of the line connecting the points $(Q, T)$ and $(1, T)$ in the $(Q, T)$ space. Therefore $p$ is the implicit unit price at which the quantity $1 - Q$ can be sold to move from $(Q, T)$ to $(1, T)$. By incentive compatibility, $p$ must lie between $\theta$ and $\bar{\theta}$ in any separating equilibrium. The strategic analysis of the buyers’ behavior induces further restrictions on $p$.

**Lemma 2** *In a separating equilibrium, $p < \bar{\theta}$ implies that $p \geq v(\theta)$.*

In the proof of Lemma 1, we showed that, if $Q < 1$, then each buyer has an incentive to deviate. By contrast, in the proof of Lemma 2, we only show that if $p < \min\{v(\theta), \bar{\theta}\}$ in a candidate separating equilibrium, then at least one buyer has an incentive to deviate. This makes it more difficult to graphically illustrate why the deviation used in Lemma 2 might be profitable. It is however easy to see why this deviation would be profitable to an entrant or, equivalently, to an inactive buyer that would not trade in equilibrium. This situation is depicted on Figure 3. The dotted line passing through $\bar{A}$ is an indifference curve for the buyers, with slope $v(\theta)$. Contrary to the conclusion of Lemma 2, the figure is drawn in such a way that this indifference curve is strictly steeper than the line segment $\bar{A}A$.

---Insert Figure 3 here---

Suppose now that the entrant offers a contract that makes available the trade $\bar{A}A$. This leaves type $\bar{\theta}$ indifferent, since she obtains the same payoff as in equilibrium by trading the aggregate allocation $(Q, T)$ together with the new contract. Type $\bar{\theta}$, by contrast, cannot gain by trading this new contract. Assuming that the entrant can break the indifference of type $\bar{\theta}$ in his favor, he earns a strictly positive payoff from trading the new contract with type $\bar{\theta}$, as the slope $p$ of the line segment $\bar{A}A$ is strictly less than $v(\theta)$. This shows that, unless $p \geq v(\theta)$, the candidate separating equilibrium is not robust to entry. The assumption on indifference breaking is relaxed in the proof of Lemma 2, which further shows that the proposed deviation is profitable to at least one buyer.

**Attracting both Types by Pivoting Around $(Q, T)$** A separating equilibrium must be robust to deviations that attract both types of the seller. This third type of deviations allows one to find a necessary condition for the existence of a separating equilibrium. When this condition fails, both types of the seller must trade the same aggregate allocations in equilibrium. We say in this case that the equilibrium is *pooling*. 
Lemma 3 If $E[v(\theta)] > \bar{\theta}$, any equilibrium is pooling, with

$$(Q, T) = (\overline{Q}, \overline{T}) = (1, E[v(\theta)]).$$

The proof of Lemma 3 consists in showing that if $E[v(\theta)] > \bar{\theta}$ in a candidate separating equilibrium, then at least one buyer has an incentive to deviate. As for Lemma 2, this makes it difficult to graphically illustrate why this deviation might be profitable. It is however easy to see why this deviation would be profitable to an entrant or, equivalently, to an inactive buyer that would not trade in equilibrium. This situation is depicted on Figure 4. The dotted line passing through $\overline{A}$ is an indifference curve for the buyers, with slope $E[v(\theta)]$. Contrary to the conclusion of Lemma 3, the figure is drawn in such a way that this indifference curve is strictly steeper than the indifference curves of type $\bar{\theta}$.

—Insert Figure 4 here—

Suppose now that the entrant offers a contract that makes available the trade $\overline{AA}'$. This leaves type $\bar{\theta}$ indifferent, since she obtains the same payoff as in equilibrium by trading the aggregate allocation $(\overline{Q}, \overline{T})$ together with the new contract. Type $\theta$ strictly gains by trading this new contract. Assuming that the entrant can break the indifference of type $\bar{\theta}$ in his favor, he earns a strictly positive payoff from trading the new contract with both types as the slope $\bar{\theta}$ of the line segment $\overline{AA}'$ is strictly less than $E[v(\theta)]$. This shows that, unless $E[v(\theta)] \leq \bar{\theta}$, the candidate equilibrium is not robust to entry. Once again, the assumption on indifference breaking is relaxed in the proof of Lemma 3, which further shows that the proposed deviation is profitable to at least one buyer.

The following result provides a partial converse to Lemma 3.

Lemma 4 If $E[v(\theta)] < \bar{\theta}$, any equilibrium is separating, with

$$(Q, T) = (1, v(\theta)) \text{ and } (\overline{Q}, \overline{T}) = (0, 0).$$

The following is an important corollary of our analysis.

Corollary 1 Each buyer’s payoff is zero in any equilibrium.

Lemmas 1 to 4 provide a full characterization of the aggregate trades that can be sustained in an equilibrium of the non-exclusive competition game. A key implication of Lemmas 3 and 4 is that the aggregate equilibrium allocation traded by the seller is generically unique.\(^9\) While each buyer always obtains a zero payoff in equilibrium, the structure of equilibrium allocations is directly affected by the severity of the adverse selection problem:

\(^9\)The non-generic case where $E[v(\theta)] = \bar{\theta}$ is discussed after Proposition 2.
Whenever $E[v(\theta)] > \bar{\theta}$, adverse section is mild, which rules out separating equilibria. Indeed, as shown in the proof of Lemma 3, if the aggregate allocation $(\overline{Q}, \overline{T})$ traded by type $\bar{\theta}$ were such that $\overline{Q} < 1$, some buyer would have an incentive to induce both types of the seller to trade this allocation, together with the additional quantity $1 - \overline{Q}$ at a unit price between $\overline{\theta}$ and $E[v(\theta)]$. Competition among buyers then bids up the price of the seller’s endowment to its average value $E[v(\theta)]$ for the buyers, a price at which both types of the seller are ready to trade. This situation is depicted on Figure 5. The dotted line passing through the origin is the equilibrium indifference curve of the buyers, with slope $E[v(\theta)]$.

—Insert Figure 5 here—

Whenever $E[v(\theta)] < \bar{\theta}$, adverse selection is severe, which rules out pooling equilibria. This reflects that type $\bar{\theta}$ is no longer ready to trade her endowment at the maximal price $E[v(\theta)]$ at which buyers would break even in such an equilibrium. More interestingly, our analysis shows that non-exclusive competition induces a specific cost of screening the seller’s type in equilibrium. Indeed, any separating equilibrium must be such that no buyer has an incentive to deviate and induce type $\theta$ to trade the aggregate allocation $(\overline{Q}, \overline{T})$, together with the additional quantity $1 - \overline{Q}$ at some mutually advantageous price. Lemma 2 shows that to eliminate any incentive for buyers to engage in such trades with type $\theta$, the implicit unit price at which this additional quantity $1 - \overline{Q}$ can be sold in equilibrium must be at least $v(\theta)$. As shown in Lemma 4, this implies at most an aggregate payoff $\{E[v(\theta)] - \bar{\theta}\}\overline{Q}$ for the buyers. Hence type $\bar{\theta}$ can trade actively in a separating equilibrium only in the non-generic case where $E[v(\theta)] = \bar{\theta}$, while type $\theta$ does not trade at all if $E[v(\theta)] < \bar{\theta}$. This situation is depicted on Figure 6. The dotted line passing through the origin is the equilibrium indifference curve of the buyers, with slope $v(\theta)$.

—Insert Figure 6 here—

### 3.2.2 Equilibrium Existence

We now establish that, in contrast with the exclusive competition game of Subsection 3.1, the non-exclusive competition game always has an equilibrium. Specifically, we show that there always exists an equilibrium in which all buyers post linear prices. In such an equilibrium, the unit price at which any quantity can be traded is equal to the expected quality of the
goods that are actively traded. Specifically, define

\[ p^* = \begin{cases} 
E[v(\theta)] & \text{if } E[v(\theta)] \geq \overline{\theta}, \\
v(\theta) & \text{if } E[v(\theta)] < \overline{\theta}. 
\end{cases} \tag{1} \]

One then has the following result.

**Proposition 2** The non-exclusive competition game always has an equilibrium in which each buyer offers the menu

\[ \{(q, t) \in [0, 1] \times \mathbb{R}_+ : t = p^*q\}, \]

and thus stands ready to buy any quantity of the good at the constant unit price \( p^* \).

In the non-generic case where \( E[v(\theta)] = \overline{\theta} \), it is easy to check that there exist two linear price equilibria, a pooling equilibrium with constant unit price \( E[v(\theta)] \) and a separating equilibrium with constant unit price \( v(\theta) \). In addition, there exists in this case a continuum of separating equilibria in which type \( \theta \) trades actively. Indeed, to sustain an equilibrium trade level \( \overline{Q} \in (0, 1) \) for type \( \overline{\theta} \), it is enough that all buyers offer to buy any quantity of the good at unit price \( v(\theta) \), and that one buyer offers in addition to buy any quantity of the good up to \( \overline{Q} \) at unit price \( E[v(\theta)] \). Both types \( \overline{\theta} \) and \( \overline{\theta} \) then sell a fraction \( \overline{Q} \) of their endowment at unit price \( E[v(\theta)] \), while type \( \overline{\theta} \) sells the remaining fraction of her endowment at unit price \( v(\theta) \). To avoid this non-generic multiplicity issue and therefore simplify the exposition, we shall assume that \( E[v(\theta)] \neq \overline{\theta} \) in the remainder of this section.

### 3.2.3 Comparison with the Exclusive Competition Model

Our analysis provides a fully strategic foundation for Akerlof’s (1970) original intuition. First, if adverse selection is severe enough, only goods of low quality are traded in equilibrium. Second, as can be seen from (1), the price \( p^* \) at which the seller can sell her endowment in equilibrium is the expectation of the value of the good to the buyers, conditional on the seller being willing to trade at this price:

\[ p^* = E[v(\theta) | \theta \leq p^*]. \]

These results contrasts sharply with the predictions of standard models of competition under adverse selection, in which, as in the exclusive competition game of Subsection 3.1, exclusivity clauses are assumed to be enforceable at no cost. Specifically, the equilibrium outcomes of the non-exclusive competition game differ in three crucial ways from that of the exclusive competition game:
- First, the exclusive competition game has an equilibrium only if the probability that the good is of high quality is low enough. By contrast, the non-exclusive competition game always has an equilibrium.

- Second, when it exists, the equilibrium of the exclusive competition game is always separating, while for certain parameter values all the equilibria of the non-exclusive competition game are pooling.

- Third, even when all equilibria of the non-exclusive competition game are separating, their structure is very different from that of the exclusive competition game. In the latter case, type $\theta$ is indifferent between her equilibrium contract and that of type $\bar{\theta}$, who trades a strictly positive fraction of her endowment. By contrast, in the former case, type $\theta$ strictly prefers her aggregate equilibrium allocation to that of type $\bar{\theta}$, who does not trade in equilibrium.

With regard to the last point, simple computations show that the threshold $\nu^e = \frac{\pi - \theta}{v(\theta) - \bar{\theta}}$ for $\nu$ below which the exclusive competition game has an equilibrium is strictly greater than the threshold $\nu^{ne} = \max \left\{ 0, \frac{\pi - v(\theta)}{v(\theta) - v(\bar{\theta})} \right\}$ for $\nu$ below which all equilibria of the non-exclusive competition game are separating. Thus if one assumes that $\nu \leq \nu^e$, so that equilibria exist under both exclusivity and non-exclusivity, two situations can arise. When $0 < \nu < \nu^{ne}$, the equilibrium is separating under both exclusivity and non-exclusivity, and more trade takes place in the former case. By contrast, when $\nu^{ne} < \nu \leq \nu^e$, the equilibrium is separating under exclusivity and pooling under non-exclusivity, and more trade takes place in the latter case. Therefore, from an ex-ante viewpoint, exclusive competition leads to a more efficient outcome under severe adverse selection, while non-exclusive competition leads to a more efficient outcome under mild adverse selection.

### 3.3 Equilibrium Menus and Latent Contracts

We now explore in more depth the structure of the menus offered by the buyers in equilibrium. We first provide equilibrium restrictions for the price of issued and traded contracts. Next, we show that a large number of latent contracts needs to be issued in equilibrium. Then, we relate our analysis to the literature on communication in common agency games. Finally, we show that the aggregate equilibrium allocations can also be sustained through non-linear price schedules.
3.3.1 Price Restrictions

Our first result provides equilibrium restrictions on the price of all issued contracts.

**Proposition 3** The unit price of any contract issued in an equilibrium of the non-exclusive competition game is at most $p^*$.

The intuition for this result is as follows. First, if $\mathbb{E}[v(\theta)] > \bar{\theta}$ and some buyer offered to purchase some quantity at a unit price above $\mathbb{E}[v(\theta)]$, any other buyer would have an incentive to induce both types of the seller to trade this contract and to sell him the remaining fraction of their endowment at a unit price slightly below $\mathbb{E}[v(\theta)]$. Second, if $\mathbb{E}[v(\theta)] < \bar{\theta}$ and some buyer offered to purchase some quantity at a unit price above $v(\theta)$, then any other buyer would have an incentive to induce type $\theta$ to trade this contract and to sell him the remaining fraction of her endowment at a unit price slightly below $v(\theta)$. As a corollary, one obtains a straightforward characterization of the price of traded contracts.

**Corollary 2** The unit price of any contract traded in an equilibrium of the non-exclusive competition game is $p^*$.

3.3.2 Latent Contracts

With these preliminaries at hand, we can investigate which contracts need to be issued to sustain the aggregate equilibrium allocations. From a strategic viewpoint, what matters for each buyer is the outside option of the seller, that is, what aggregate allocations she can achieve by trading with the other buyers only. For each buyer $i$, and for each menu profile $(C_1, \ldots, C^n)$, this is described by the set of aggregate allocations that remain available if buyer $i$ withdraws his menu offer $C^i$. One first has the following result.

**Proposition 4** In any equilibrium of the non-exclusive competition game, the aggregate allocation $(1, p^*)$ remains available if any buyer withdraws his menu offer.

The aggregate equilibrium allocation must therefore remain available even if a buyer deviates from his equilibrium menu offer. The reason is that this buyer would otherwise have an incentive to offer both types to sell their whole endowment at a price slightly below $\mathbb{E}[v(\theta)]$ (if $\mathbb{E}[v(\theta)] > \bar{\theta}$), or to offer type $\bar{\theta}$ to sell her whole endowment at price $v(\theta)$ while offering type $\bar{\theta}$ to sell a smaller fraction of her endowment on more advantageous terms (if $\mathbb{E}[v(\theta)] < \bar{\theta}$). The flip side of this observation is that no buyer is essential in providing the seller with her aggregate equilibrium allocation. This rules out standard Cournot outcomes.
in which the buyers would simply share the market and in which all issued contracts would actively be traded by some type of the seller, as in Biais, Martimort and Rochet (2000). As an illustration, when there are two buyers, there is no equilibrium in which each buyer would only offer to purchase half of the seller’s endowment.

Because of the non-exclusivity of competition, equilibrium in fact involves much more restrictions on menus offers than those prescribed by Propositions 3 and 4. For instance, if \( E[v(\theta)] > \bar{\theta} \), there is no equilibrium in which each buyer only offers the allocation \((1, E[v(\theta)])\) besides the no-trade contract. Indeed, any buyer could otherwise deviate by offering to purchase a quantity \( \bar{q} < 1 \) at some price \( \bar{t} \in (E[v(\theta)] - \bar{\theta}(1 - \bar{q}), E[v(\theta)] - \theta(1 - \bar{q})) \). By construction, this is a cream-skimming deviation that attracts only type \( \bar{\theta} \), and that yields the deviating buyer a payoff

\[
\nu[v(\bar{\theta})\bar{t} - \bar{t}] > \nu\{v(\bar{\theta})\bar{q} - E[v(\theta)] + \theta(1 - \bar{q})\},
\]

which is strictly positive for \( \bar{q} \) close enough to one. To block such deviations, latent contracts must be issued that are not actively traded in equilibrium but which the seller has an incentive to trade if some buyer attempts to break the equilibrium. In order to play this deterrence role, the corresponding latent allocations must remain available if any buyer withdraws his menu offer. For instance, in the case \( E[v(\theta)] > \bar{\theta} \), the cream-skimming deviation described above is blocked if the quantity \( 1 - \bar{q} \) can always be sold at unit price \( E[v(\theta)] \) at the deviation stage, since both types of the seller then have the same incentives to trade the contract proposed by the deviating buyer. This corresponds to the linear price equilibrium described in Proposition 2. In this equilibrium, the number of latent contracts is large; indeed, the menus offered by the buyers are infinite collections of contracts. The following result shows that this is a robust feature of any equilibrium.

**Proposition 5** *In any equilibrium of the non-exclusive competition game, there are infinitely many aggregate allocations that remain available if any buyer withdraws his menu offer.*

The intuition for this result is as follows. As suggested by the above discussion, one of the roles of latent contracts is to prevent cream-skimming deviations that only attract type \( \bar{\theta} \). Each buyer issues these contracts anticipating that type \( \bar{\theta} \) will have an incentive to trade them following a cream-skimming deviation by any of the other buyers. Now, there are infinitely many such deviations. Consistent with this, the proof of Proposition 5 proceeds by showing that if only finitely many latent contracts were offered at equilibrium by buyers \( j \neq i \), it would be possible to construct a cream-skimming deviation for buyer \( i \) that would yield him a strictly positive payoff.
3.3.3 Menus, Communication, and the Failure of the Revelation Principle

Our results on the necessary role played by latent contracts to support equilibrium allocations have a natural interpretation in the language of the common agency literature, whose aim is to analyze situations where several principals compete through mechanisms for the services of a single agent.\(^{10}\) In our context, given a set \(\mathcal{M}^i\) of messages from the seller to buyer \(i\), a (deterministic) mechanism for buyer \(i\) is a mapping \(\pi^i : \mathcal{M}^i \rightarrow [0, 1] \times \mathbb{R}_+\) that associates to each message sent by the seller to buyer \(i\) a quantity-transfer pair or contract. Let \(\Pi^i(\mathcal{M}^i)\) be the set of mechanisms available to buyer \(i\) and \(\Pi(\mathcal{M}^1, \ldots, \mathcal{M}^n) = \prod_{i=1}^n \Pi^i(\mathcal{M}^i)\).

In the common agency game relative to \(\Pi(\mathcal{M}^1, \ldots, \mathcal{M}^n)\), the seller takes her participation and communication decisions after having observed the profile of mechanisms \((\pi^1, \ldots, \pi^n)\) offered by the different buyers. Peters (2001) and Martimort and Stole (2002) have proven the following result, often referred to as the Delegation Principle: for any equilibrium outcome relative to the space of mechanisms \(\Pi(\mathcal{M}^1, \ldots, \mathcal{M}^n)\), there exists an equilibrium that induces the same outcome in the game where buyers offer menus of contracts, provided any size restrictions on the original message spaces \(\mathcal{M}^i\)'s are translated into corresponding restrictions on the allowed menus.

In our setting, buyers compete over menus of contracts for the trade of a divisible good. From Proposition 5, we know that equilibrium menus should contain an infinite number of contracts. In view of the Delegation Principle, this suggests that to support our Akerlof-like equilibrium outcomes when competition over mechanisms is considered, a rich structure of communication has to be postulated. That is, an infinite number of messages should be available to the seller, allowing her to effectively act as a coordinating device among buyers, so as to guarantee the existence of an equilibrium. In particular, these allocations cannot be supported if buyers are restricted to compete through simple direct mechanisms of the form \(\hat{\gamma}^i : \{\theta, \theta\} \rightarrow [0, 1] \times \mathbb{R}_+\) through which the seller can only communicate her type to the buyers. Indeed, if the buyers are restricted to direct mechanisms, only a finite set of offers will be available to the seller, which, as we have seen, makes it impossible to support our equilibrium allocations. Critically, direct mechanisms do not provide enough flexibility to buyers to make a strategic use of the seller in deterring cream-skimming deviations.\(^ {11}\)

\(^{10}\)To use the terminology of Bernheim and Whinston (1986b), our non-exclusive competition game is a delegated common agency game, as the seller can choose a strict subset of buyers with whom she wants to trade. Thus common agency is a choice variable that is delegated to the seller. See for instance Martimort (2007) for a recent overview of the common agency literature.

\(^{11}\)This difficulty would remain intact even if stochastic direct mechanisms were allowed. Indeed, in any pure strategy equilibrium of a direct mechanism game where buyers use stochastic mechanisms, the seller will send messages before observing the realization of uncertainty. At equilibrium, only a finite number of
The possibility to support equilibrium allocations relative to an arbitrary set of indirect mechanisms, but not in the corresponding direct mechanism game, has been acknowledged as a failure of the Revelation Principle in common agency games, and documented in purely abstract game-theoretic examples. One of the contribution of our analysis is to exhibit a natural and relevant economic setting that exhibits this feature. Note furthermore that, in contrast with the exclusive competition context, where market equilibria can without any loss of generality be characterized through simple direct mechanisms, the restriction to such mechanisms turns out to be devastating under non-exclusivity: indeed, in this context, an immediate implication of our analysis is that no allocation can be supported at equilibrium in the direct mechanism game.

3.3.4 Non-Linear Equilibria

We now show that one can also construct non-linear equilibria in which latent contracts are issued at a unit price different from that of the aggregate allocation that is traded in equilibrium.

**Proposition 6** The following holds:

(i) If \( \mathbb{E}[v(\theta)] > \bar{\theta} \), then, for each \( \phi \in [\bar{\theta}, \mathbb{E}[v(\theta)]] \), the non-exclusive competition game has an equilibrium in which each buyer offers the menu

\[
\left\{ (q, t) \in [0, \frac{v(\bar{\theta}) - \mathbb{E}[v(\theta)]}{v(\bar{\theta}) - \phi}] \times \mathbb{R}_+ : t = \phi q \right\} \cup \{(1, \mathbb{E}[v(\theta)])\}.
\]

(ii) If \( \mathbb{E}[v(\theta)] < \bar{\theta} \), then, for each \( \psi \in (v(\bar{\theta}), v(\bar{\theta}) + \frac{\bar{\theta} - \mathbb{E}[v(\theta)]}{1 - \nu}] \), the non-exclusive competition game has an equilibrium in which each buyer offers the menu

\[
\{(0, 0)\} \cup \left\{ (q, t) \in \left[ \frac{\psi - v(\bar{\theta})}{\psi}, 1 \right] \times \mathbb{R}_+ : t = \psi q - \psi + v(\bar{\theta}) \right\}.
\]

This result shows that the unique aggregate equilibrium allocation can also be supported through non-linear prices. In such equilibria, the price each buyer is willing to pay for an additional unit of the good is not the same for all quantities purchased. For instance, in the equilibrium for the severe adverse selection case described in Proposition 6(i), buyers are not ready to pay anything for all quantities up to the level \( \psi - v(\bar{\theta}) \psi \), while they are ready to lotteries over allocations will be offered. Bilateral risk-neutrality then makes this situation equivalent to one in which only deterministic allocations are proposed. One should however observe that it is problematic to interpret stochastic mechanisms in our model, where the seller operates under a capacity constraint.

pay $\psi$ for each additional unit of the good above this level. The price schedule posted by each buyer is such that, for any $q < 1$, the unit price $\max\{0, \psi - \frac{\psi - v(\theta)}{q}\}$ at which he offers to purchase the quantity $q$ is strictly below $\theta$, while the marginal price $\psi$ at which he offers to purchase an additional unit given that he has already purchased a quantity $q \geq \frac{\psi - v(\theta)}{\psi}$ is strictly above $\theta$. Therefore the equilibrium budget set of the seller

$$\left\{(Q, T) \in [0, 1] \times \mathbb{R}_+: Q = \sum_i q^i \text{ and } T \leq \sum_i t^i \text{ where } (q^i, t^i) \in C^i \text{ for all } i\right\}$$

is not convex in this equilibrium. As a result of this, the seller has a strict incentive to deal with a single buyer: market equilibria can be supported with a single active buyer, provided that the other buyers coordinate by offering appropriate latent contracts. It follows in particular that non-exclusive competition does not necessarily entail that the seller enters into multiple contracting relationships.

This result contrasts with recent work on competition in non-exclusive mechanisms under incomplete information, where attention is typically restricted to equilibria in which the informed agent has a convex budget set in equilibrium, or, what amounts to the same thing, where the set of allocations available to her is the frontier of a convex budget set. In our model, this would for instance arise if all buyers posted concave price schedules. It is therefore interesting to notice that, as a matter of fact, our non-exclusive competition game has no equilibrium in which each buyer $i$ posts a strictly concave price schedule $T^i$. The reason is that the aggregate price schedule $\Sigma$ defined by $\Sigma(Q) = \sup \{\sum_i T^i(q^i) : \sum_i q^i = Q\}$ would otherwise be strictly concave in the aggregate quantity traded $Q$. This would in turn imply that contracts are issued at a unit price strictly above $\Sigma(1)$, which, as shown by Proposition 3, is impossible in equilibrium.

A further implication of Proposition 6 is that latent contracts supporting the equilibrium allocations can be issued at a profitable price for the issuer. For instance, in the equilibrium described in Proposition 6(ii), any contract in the set $\left\{\left[\frac{\psi - v(\theta)}{\psi}, 1\right] \times \mathbb{R}_+ : t = \psi q - \psi + v(\theta)\right\}$ would yield its issuer a strictly positive payoff, even if it were traded by type $\theta$ only. In equilibrium, no mistakes occur, and buyers correctly anticipate that none of these contracts will be traded. Nonetheless, removing these contracts would break the equilibrium. One should notice in that respect that the role of latent contracts in non-exclusive markets has usually been emphasized in complete information environments in which the agent does not

trade efficiently in equilibrium.\textsuperscript{14} In these contexts, latent contracts can never be profitable. Indeed, if they were, there would always be room for proposing an additional latent contract at a less profitable price and induce the agent to accept it. In our model, by contrast, type $\theta$ sells her whole endowment in equilibrium. It follows from Proposition 3 that there cannot be any latent contract that would make losses. In addition, there is no incentive for any single buyer to raise the price of these contracts and make the seller willing to trade them.

4 The Continuous-Type Case

In this section, we show that the results derived so far extend to the case where the seller’s type is continuously distributed. The model remains the same as in Section 2, but from now on we assume that the seller’s type $\theta$ has a continuously differentiable distribution $F$ with strictly positive density $f$ over a compact interval $[\theta, \bar{\theta}]$ of $\mathbb{R}_{++}$. The valuation function $v$ is assumed to be continuous; we will sometimes assume that $v$ is increasing, as is natural when the seller’s private information bears on the quality of the good. We shall look for equilibria that verify a simple refinement called conservativeness. Specifically, a Perfect Bayesian Equilibrium is conservative if a buyer cannot profitably deviate by adding one contract to his equilibrium menu, assuming that those types of the seller that would strictly lose from trading the new contract do not change their behavior compared to the equilibrium path. Hence conservativeness requires that the seller does not play an active role in deterring deviations by a buyer if she does not benefit from doing so.\textsuperscript{15} This requirement was not needed in the study of the two-type case, because we were able to perfectly control the trades of each type following a deviation. This is more difficult with a continuum of types, and for the sake of simplicity we choose to reinforce the equilibrium concept.

4.1 Monopsony

As a preliminary, it is useful to consider the monopsony case with a single buyer. Suppose first that the monopsony simply offers to buy the seller’s whole endowment at price $p$. Because only types below $p$ accept this offer, the monopsony’s payoff is then

$$w(p) = \int_\theta^p (v(\theta) - p) \, dF(\theta). \quad (2)$$

\textsuperscript{14}See for instance Hellwig (1983), Martimort and Stole (2003), Bisin and Guaitoli (2004) or Attar and Chassagnon (2009).

\textsuperscript{15}Observe that this refinement does not restrict in any way the behavior of the seller following a deviation by a buyer who withdraws some or all of his equilibrium offers. By contrast, in any subgame where the refinement has bite, the equilibrium utility of the seller remains available no matter her type.
The function $w$ is continuous, vanishes at $\theta$, and is strictly decreasing beyond $\bar{\theta}$. It thus has a maximum $w^m \geq 0$ that is attained at some point in $[\underline{\theta}, \bar{\theta}]$. To avoid ambiguities, define the monopsony price $p^m$ as the highest such point. Now, assume that the monopsony can offer arbitrary menus of contracts, with quantities in $[0, 1]$. From the Revelation Principle, there is no loss of generality in focusing on direct revelation mechanisms $(Q, T) : [\underline{\theta}, \bar{\theta}] \rightarrow [0, 1] \times \mathbb{R}_+$ that stipulate a quantity and a transfer as a function of the seller’s report of her type.\footnote{It is easy to check that, because of linear preferences, the monopsony cannot improve his payoff by offering a stochastic mechanism.} The monopsony maximizes his payoff

$$\int_{\underline{\theta}}^{\bar{\theta}} [v(\theta)Q(\theta) - T(\theta)] \, dF(\theta),$$

subject to the seller’s incentive compatibility and individual rationality constraints

$$T(\theta) - \theta Q(\theta) \geq T(\theta') - \theta Q(\theta'),$$

$$T(\theta) - \theta Q(\theta) \geq 0,$$

for all $((\theta, \theta') \in [\underline{\theta}, \bar{\theta}]^2$. In line with Samuelson (1984), we have the following result.

**Lemma 5** Even when allowed to trade quantities in $[0, 1]$, the monopsony cannot do better than offering to buy the seller’s whole endowment at the price $p^m$.

Hence allowing to trade any fraction of the seller’s endowment has no impact on the solution to the monopsony problem. This may seem intuitive, as preferences are linear. Nevertheless one must be cautious; as we now show, this option does impact equilibria when buyers compete in exclusive contracts, despite the linearity of preferences.

### 4.2 Exclusive Competition

Suppose first that buyers are restricted to bid for the seller’s whole endowment. Define $p^*$ as the supremum of those $p$ such that $w(p) > 0$, setting $p^* = \underline{\theta}$ if there are none. Thus $p^*$ is the highest price at which the seller’s whole endowment can be profitably bought. As $w$ is continuous, we know that $w(p^*) = 0$, which can be rewritten under the more familiar form:

$$p^* = E[v(\theta) \mid \theta \leq p^*].$$

That is, $p^*$ satisfies the property put forward by Akerlof (1970): at price $p^*$ competitive supply equals competitive demand, all seller’s types below $p^*$ sell their whole endowment,
while seller’s types above \( p^* \) do not trade at all. To avoid discussing non-generic cases we assume that \( w(p) < 0 \) whenever \( p > p^* \). Arguing as in Mas-Colell, Whinston and Green (1995, Proposition 13.B.1), one can then show that \( p^* \) is the price that prevails in equilibrium when buyers can only bid for the seller’s whole endowment.

Let us now allow for arbitrary trades, but restrict the seller to trade with a single buyer, as in the exclusive competition game of Subsection 3.1. Recall that in the two-type case studied then, equilibria under exclusive competition were similar to those derived by Rothschild and Stiglitz (1976): equilibria are separating, and exist only under restrictive assumptions on the seller’s type distribution. In the continuous-type case, non-existence of equilibria turns out to be the rule, as we now explain.\(^{17}\) The intuition for this result is that exclusive contracting allows buyers to design very precisely their offers, so as to target the seller’s types whose trades are profitable to them. In particular, when a quantity strictly between zero and one is traded, buyers can deviate by proposing to trade a lower or a higher quantity. This flexibility implies in turn the very strong zero-profit condition that, in equilibrium, the buyers’ aggregate payoff must be zero on any type who trades such a quantity.\(^ {18}\) Along with the seller’s incentive compatibility condition, this greatly reduces the set of possible equilibrium outcomes. When \( v \) is strictly increasing, all such allocations can be shown to be vulnerable to a pooling offer to buy the whole endowment from an interval of types.

**Proposition 7** Suppose that \( v \) is strictly increasing. Then all conservative equilibria of the exclusive competition game feature no trade. In particular, no equilibrium exists if the monopsony payoff \( w^m \) is strictly positive.

### 4.3 Non-Exclusive Competition

By contrast, our first result in this section is that an equilibrium always exists under non-exclusive competition.

**Proposition 8** The non-exclusive competition game always has a conservative equilibrium in which each buyer offers the menu

\[
\{(q, t) \in [0, 1] \times \mathbb{R}_+ : t = p^* q\},
\]

and thus stands ready to buy any quantity of the good at the constant unit price \( p^* \).

---

\(^{17}\) Proposition 7 below is actually an instance of a folk theorem in the competitive screening literature, see for instance Riley (2001, Subsection 3.1).

\(^{18}\) On the set of types who trade their whole endowment, one can only show that the buyers’ aggregate payoff must be on average zero.
Hence equilibria always exists, even when $v$ is not monotonic. Observe that this linear price equilibrium induces the Akerlof (1970) outcome: all seller’s types below $p^*$ sell their whole endowment, while seller’s types above $p^*$ do not trade at all. Our second result is that this must be the case in any conservative equilibrium.

**Proposition 9** In any conservative equilibrium of the non-exclusive competition game, the aggregate equilibrium allocations satisfy

$$(Q(\theta), T(\theta)) = (1, p^*) \text{ if } \theta < p^* \text{ and } (Q(\theta), T(\theta)) = (0, 0) \text{ if } \theta > p^*.$$  

Since $p^* = \mathbb{E}[v(\theta)| \theta \leq p^*]$, each buyer’s payoff is zero in any conservative equilibrium.

The intuition for this result can be easily understood in the context of a free-entry equilibrium. Suppose that some type $\theta_1 < p^*$ sells a quantity $Q_1 < 1$. Since the aggregate quantity traded by the seller must by incentive compatibility be a decreasing function of her type, it follows from the definition of $p^*$ that one can moreover choose $\theta_1$ such that $w(\theta_1) > 0$. Then an entrant could offer to buy $1 - Q_1$ at a unit price $\theta_1$. Clearly all types above $\theta_1$ would reject this new offer. By contrast, type $\theta_1$ is indifferent: if she accepts the offer, she sells $1 - Q_1$ units to the entrant, and she sells as before the remaining fraction $Q_1$ of her endowment to the other buyers. Because types below $\theta_1$ are more eager to sell, they must also choose to sell their whole endowment, and therefore all accept the new offer. The entrant’s payoff would then be $(1 - Q_1)w(\theta_1) > 0$, meaning that entry would be profitable. In the proof of Proposition 9, we show that a deviation that makes the trade $((1 - Q_1), \theta_1(1 - Q_1))$ available, in addition to the trades already offered, is profitable to at least one buyer. As in our analysis of the two-type case, this buyer proposes a larger trade by pivoting on the trades offered by the other buyers.

Proposition 9 implies that aggregate quantities and transfers are uniquely determined in equilibrium, and correspond to those that would obtain in the classical Akerlof (1970) model. A distinctive feature of our model, though, is that buyers are strategic and compete for the divisible good offered by the seller by proposing to her non-exclusive menus of contracts. Our results thus provide a solid game-theoretic foundation to Akerlof’s (1970) predictions. Finally, observe that since $p^* \geq p^m$, there is more trade under non-exclusive competition than in the monopsony case, which does not come as a surprise.

### 4.4 Equilibrium Menus

We now explore the structure of the menus offered by the buyers in equilibrium, and in particular the role and necessity of latent contracts. Our first results parallel Proposition 3
and Corollary 2 and provide equilibrium restrictions on the price of all issued and traded contracts.

**Proposition 10** The unit price of any contract issued in a conservative equilibrium of the non-exclusive competition game is at most $p^*$.

**Corollary 3** The unit price of any contract traded in a conservative equilibrium of the non-exclusive competition game is $p^*$.

As in the two-type case, these results illustrate how competition disciplines the buyers in our model: even though they are allowed to propose arbitrary menus of contracts, in equilibrium they end up trading at the same price. Even non-traded contracts must be issued at a unit price at most equal to $p^*$: otherwise one of the buyers could strategically use such a contract and pivot on it so as to increase his payoff. It should be noted that if $p^* \leq \bar{\theta}$, this last result can be proven without relying on a pivoting argument: indeed, if a contract with unit price strictly above $p^*$ were issued, then type $p^*$ would have a strict incentive to trade this contract instead of those that she trades in equilibrium, and so would all types slightly below $p^*$ by continuity of the seller’s preferences with respect to her type.

We now investigate which contracts need to be issued to sustain the aggregate equilibrium allocations. In line with Proposition 4, one first has the following result.

**Proposition 11** In any conservative equilibrium of the non-exclusive competition game, the aggregate allocation $(1, p^*)$ remains available if any buyer withdraws his menu offer.

When $E[v(\theta)] > \bar{\theta}$, the proof of this result is identical to that of its two-type counterpart. However, when $E[v(\theta)] < \bar{\theta}$, the proof is more involved in the continuous-type case. Indeed, unlike in the two-type case, where there is a wedge between the type $\theta$ of the active seller and the equilibrium price $v(\theta)$ at which all trades take place, in the continuous-type case the equilibrium price is equal to the type $p^*$ of the marginal seller. This makes it impossible for a buyer to screen types $\theta > p^*$ from types $\theta \leq p^*$ at the deviation stage. Instead, we show that if the allocation $(1, p^*)$ did not remain available if a buyer removed his equilibrium offer, then for $\varepsilon > 0$ small enough this buyer could pivot on the aggregate allocation that type $p^* - \varepsilon < p^*$ would optimally trade with buyers $j \neq i$ only, and secure a strictly positive payoff by trading with types $\theta < p^* - \varepsilon$.

We now argue that many contracts need to be issued to support equilibria, even though each of these contracts has at most unit price $p^*$. Suppose for simplicity that the function
is strictly increasing, and consider types close to but below \( p^* \). Because these types are less eager to sell than type \( p^* \), it is possible to deviate by offering to buy a quantity slightly below one at a unit price slightly above \( p^* \). The fact that \( v \) is strictly increasing ensures that the deviating buyer would obtain a positive payoff from trading such a contract with the types in question. However, the distinctive feature of non-exclusive competition is that other types may also be attracted by the deviating buyer’s offer. Indeed, these types could accept the deviation, and sell the remaining part of their endowment to non-deviating buyers if the latter offer contracts that allow to trade small quantities at a price close enough to \( p^* \). This in turn proves necessary to support equilibria, as we now show.

**Proposition 12** Suppose that \( v \) is strictly increasing. Then, in any conservative equilibrium of the non-exclusive competition game, there exists \( Q_0 > 0 \) such that it remains possible to trade any quantity below \( Q_0 \) if any buyer withdraws his menu offer.

Proposition 12 implies that in equilibrium many contracts, in fact a continuum of them, must be available. A similar conclusion was derived in the two-type case, though in the case where \( E[v(\theta)] < \bar{\theta} \), we only established the necessity of a countably infinite number of contracts. A closer examination of the proof however reveals that the result depends on whether there are at least two types that trade in equilibrium. In that respect, the two-type case with \( E[v(\theta)] < \bar{\theta} \) is somewhat special, because only one type of the seller is trading in equilibrium.

Unlike in the two-type case, one cannot conclude from the fact that an infinite number of contracts must be available in equilibrium that latent contracts are necessary to support equilibria. Indeed, the contracts characterized in Proposition 12 may be traded in equilibrium by some types of sellers. It turns out that equilibria without latent contracts do exist. In fact, unlike in the two-type case, the aggregate equilibrium allocations characterized in Proposition 9 can be supported in an equilibrium of the direct mechanism game. To see this, suppose that each buyer \( i \) proposes the seller to trade a quantity \( q^i(\hat{\theta}) \) at unit price \( p^* \) if she reports type \( \hat{\theta} \) to him, where the functions \((q^1, \ldots, q^n)\) satisfy

(i) \( \sum_i q_i(\theta) = 1 \) for all \( \theta < p^* \) and \( \sum_i q_i(\theta) = 0 \) for all \( \theta > p^* \);

(ii) \( \int_{\theta}^{p^*} [v(\theta) - p^*]q^i(\theta) dF(\theta) = 0 \) for all \( i \);

(iii) \( q^i([\theta, \bar{\theta}]) = [0, 1] \) for all \( i \).

Property (i) ensures that each type of the seller trades her whole endowment or refrain from trading altogether, as in the Akerlof (1970) outcome characterized in Proposition 9. Next,
property (ii) ensures that each buyer obtains a zero payoff. Finally, property (iii) ensures that all contracts in \( \{(q, t) \in [0, 1] \times \mathbb{R}_+: t = p^*q\} \) are indeed traded in equilibrium by at least one type. Therefore there are no latent contracts. Finally these offers indeed form an equilibrium of the direct mechanism game, from Proposition 8.

To speak frankly, we think that such a construction is artificial, as it requires different types of the seller to behave differently when they in fact sell the same aggregate quantity for the same aggregate transfer. One alternative would be to allow the seller to randomize over the quantities that she trades with different buyers; one is then back to the conclusion that latent contracts are strictly speaking not needed. Notice however that this candidate is not an equilibrium in direct mechanisms, as the quantity traded by any buyer depends not only on the seller’s type, but also on the result of the seller’s randomization.

5 Conclusion

In this paper, we have studied a simple imperfect competition model of trade under adverse selection. When competition is exclusive, the existence of equilibria is problematic, while equilibria always exist when competition is non-exclusive. In this latter case, aggregate quantities and transfers are generically unique, and correspond to the allocations that obtain in Akerlof’s (1970) model. Linear price equilibria can be constructed in which buyers stand ready to purchase any quantity at a constant unit price. One can also construct equilibria in which only one buyer trades with the seller.

The fact that possible market outcomes tightly depend on the nature of competition suggests that the testable implications of competitive models of adverse selection should be evaluated with care. Indeed, these implications are typically derived from the study of exclusive competition models, such as Rothschild and Stiglitz’s (1976) two-type model of insurance markets. By contrast, our analysis shows that more competitive outcomes can be sustained in equilibrium under non-exclusive competition, and that these outcomes can involve a substantial amount of pooling.

These results offer new insights into the empirical literature on adverse selection. For instance, several studies have taken to the data the predictions of theoretical models of insurance provision, without reaching clear conclusions. Cawley and Philipson (1999) argue that there is little empirical support for the adverse selection hypothesis in life insurance. In particular, they find no evidence that marginal prices raise with coverage. Similarly, Finkelstein and Poterba (2004) find that marginal prices do not significantly differ across

\[\text{References}\]

\[19\text{See Chiappori and Salanié (2003) for a survey of this literature.}\]
annuities with different initial annual payments. The theoretical predictions tested by these authors are however derived from models of exclusive competition, while our results clearly indicate that they do not hold when competition is non-exclusive, as in the case of life insurance or annuities. Indeed, non-exclusive competition might be one explanation for the limited evidence of screening and the prevalence of nearly linear pricing schemes on these markets. As a result, more sophisticated procedures need to be designed in order to test for the presence of adverse selection in markets where competition is non-exclusive.

\footnote{Chiappori, Jullien, Salanié and Salanié (2006) have derived general tests based on a model of exclusive competition, that they apply to the case of car insurance.}
Appendix

Proof of Proposition 1. The proof follows more or less standard lines (see for instance Mas-Colell, Whinston and Green (1995, Chapter 13, Section D)) and goes through a series of steps.

**Step 1** Denote by \((q, t)\) and \((\bar{q}, \bar{t})\) the contracts traded by the two types of the seller in equilibrium. These contracts must satisfy the following incentive constraints:

\[
\begin{align*}
&\bar{t} - \theta \bar{q} \geq \bar{t} - \theta \bar{q}, \\
&t - \theta q \geq t - \theta q.
\end{align*}
\]

Since the buyers always have the option not to trade, each of them must obtain at least a zero payoff in equilibrium. Suppose that some buyer’s equilibrium payoff is strictly positive. Then the buyers’ aggregate equilibrium payoff is strictly positive,

\[
\nu[v(\bar{\theta})\bar{q} - \bar{t}] + (1 - \nu)[v(\theta)q - t] > 0.
\]

Any buyer \(i\) obtaining less than half of this amount in equilibrium can deviate by offering a menu consisting of the no-trade contract and of two new contracts. The first one is

\[
\zeta^i(\varepsilon) = (q, t + \varepsilon),
\]

for some strictly positive number \(\varepsilon\), and is designed to attract type \(\theta\). The second one is

\[
\zeta^i(\varepsilon) = (\bar{q}, \bar{t} + \varepsilon),
\]

for some strictly positive number \(\varepsilon\), and is designed to attract type \(\theta\). To ensure that type \(\theta\) trades \(\zeta^i(\varepsilon)\) and type \(\bar{\theta}\) trades \(\zeta^i(\varepsilon)\) with him, buyer \(i\) can choose \(\varepsilon\) to be equal to \(\varepsilon\) when both types’ equilibrium incentive constraints are simultaneously binding or slack, and choose \(\varepsilon\) and \(\varepsilon\) to be different but close enough to each other when one of these constraints is binding and the other is slack. The change in buyer \(i\)’s payoff induced by this deviation is at least

\[
\frac{1}{2} \{\nu[v(\bar{\theta})\bar{q} - \bar{t}] + (1 - \nu)[v(\theta)q - t]\} - \nu \varepsilon - (1 - \nu)\varepsilon,
\]

which is strictly positive for \(\varepsilon\) and \(\varepsilon\) close enough to zero. Thus each buyer’s payoff is zero in any equilibrium.

**Step 2** Suppose that there exists a pooling equilibrium with both types of the seller trading the same contract \((q^p, t^p)\). It follows from Step 1 that \(t^p = E[v(\theta)]q^p\) and that both
types of the seller must trade with the same buyer \( j \). Any buyer \( i \neq j \) can deviate by offering a menu consisting of the no-trade contract and of the contract

\[
\overline{c}^i(\varepsilon) = (q^p - \varepsilon, t^p - \theta \varepsilon (1 + \varepsilon)),
\]

for some strictly positive number \( \varepsilon \). Trading \( \overline{c}^i(\varepsilon) \) decreases type \( \theta \)'s payoff by \( \theta \varepsilon^2 \) compared to what she obtains by trading \((q^p, t^p)\) with buyer \( j \). Hence type \( \theta \) does not trade \( \overline{c}^i(\varepsilon) \) following buyer \( i \)'s deviation. By contrast, if \( \varepsilon < \frac{\theta}{2} - 1 \), trading \( \overline{c}^i(\varepsilon) \) allows type \( \theta \) to increase her payoff by \( [\theta - (1 + \varepsilon)\theta]\varepsilon \) compared to what she obtains by trading \((q^p, t^p)\) with buyer \( j \). Hence type \( \theta \) trades \( \overline{c}^i(\varepsilon) \) following buyer \( i \)'s deviation. The payoff for buyer \( i \) induced by this deviation is

\[
\nu \{ v(\overline{\theta})q^p - t^p - [v(\theta) - \theta (1 + \varepsilon)]\varepsilon \},
\]

which is strictly positive for \( \varepsilon \) close enough to zero since \( t^p = E[v(\theta)]q^p \) and \( v(\overline{\theta}) > E[v(\theta)] \). This, however, is impossible by Step 1. Thus any equilibrium must be separating, with the two types of the seller trading different contracts.

**Step 3** Suppose that \( v(\overline{\theta})q > t \), so that the contract \((q, t)\) yields the buyer who trades it with type \( \overline{\theta} \) a strictly positive payoff. Any buyer \( i \) can deviate by offering a menu consisting of the no-trade contract and of the contract

\[
c^i(\varepsilon) = (q - \varepsilon, t - \theta \varepsilon (1 + \varepsilon)),
\]

for some strictly positive number \( \varepsilon \). Type \( \theta \) trades \( c^i(\varepsilon) \) following buyer \( i \)'s deviation, and also possibly type \( \overline{\theta} \). The payoff for buyer \( i \) induced by this deviation is thus at least

\[
(1 - \nu)[v(\overline{\theta})q - t - \varepsilon],
\]

which is strictly positive for \( \varepsilon \) close enough to zero if \( v(\overline{\theta})q > t \). Since this is impossible by Step 1, it must be that \( t \geq v(\overline{\theta})q \). Suppose next that \( v(\overline{\theta})q > \overline{t} \), so that the contract \((\overline{q}, \overline{t})\) yields the buyer \( j \) who trades it with type \( \overline{\theta} \) a strictly positive payoff. Any buyer \( i \neq j \) can deviate by offering a menu consisting of the no-trade contract and of the contract

\[
\overline{c}^i(\varepsilon) = (\overline{q} - \varepsilon, \overline{t} - \theta \varepsilon (1 + \varepsilon)),
\]

for some strictly positive number \( \varepsilon \). As in Step 2, it is easy to check that type \( \theta \) does not trade \( \overline{c}^i(\varepsilon) \) following buyer \( i \)'s deviation, while type \( \overline{\theta} \) does so provided \( \varepsilon < \frac{\theta}{2} - 1 \). The payoff for buyer \( i \) induced by this deviation is

\[
\nu \{ v(\overline{\theta})\overline{q} - \overline{t} - [v(\theta) - \theta (1 + \varepsilon)]\varepsilon \},
\]
which is strictly positive for $\varepsilon$ close enough to zero if $v(\theta)q > \bar{t}$. Since this is impossible by Step 1, it must be that $\bar{t} \geq v(\theta)q$. This, along with the facts that $\bar{t} \geq v(\theta)q$ and that the buyers’ aggregate equilibrium payoff is zero, implies that $\bar{t} = v(\theta)q$ and $\bar{t} = v(\theta)q$. Thus the contracts $(q, \bar{t})$ and $(\bar{q}, \bar{t})$ are traded at unit prices $v(\theta)$ and $v(\theta)$, and no cross-subsidization across types can take place in equilibrium.

**Step 4** Suppose that type $\theta$ sells a quantity $q < 1$ in equilibrium. Any buyer $i$ can deviate by offering a menu consisting of the no-trade contract and of the contract

$$c^i(\varepsilon) = (1, \bar{t} + [v(\theta) - \varepsilon](1 - q)),$$

for some strictly positive number $\varepsilon$. As long as $\varepsilon < v(\theta) - \theta q$, trading $c^i(\varepsilon)$ allows type $\theta$ to increase her payoff by $[v(\theta) - \theta - \varepsilon](1 - q)$ compared to what she obtains by trading $(q, \bar{t})$. Hence type $\theta$ trades $c^i(\varepsilon)$ following buyer $i$’s deviation, and also possibly type $\bar{\theta}$. The payoff for buyer $i$ induced by this deviation is thus at least

$$(1 - \nu)[v(\theta) - \bar{t} - [v(\theta) - \varepsilon](1 - q)] = (1 - \nu)(1 - q)\varepsilon,$$

where use was made of the fact that $\bar{t} = v(\theta)q$ by Step 3. Since $\varepsilon > 0$, this payoff is strictly positive, which is impossible by Step 1. Thus type $\theta$ sells her whole endowment in any equilibrium, and $(q, \bar{t}) = (q^e, \bar{t}^e)$ as defined in Proposition 1.

**Step 5** The contract $(\bar{q}^e, \bar{t}^e)$ is characterized by two properties: it has a unit price $v(\theta)$ and type $\theta$ is indifferent between $(q^e, \bar{t}^e)$ and $(\bar{q}^e, \bar{t}^e)$. One cannot have $\bar{q} > \bar{q}^e$, for $(\bar{q}, \bar{t})$ is traded at unit price $v(\theta)$ by Step 3, and any contract in which a quantity strictly higher than $\bar{q}^e$ is traded at unit price $v(\theta)$ is strictly preferred by type $\theta$ to $(q^e, \bar{t}^e)$. Now, suppose that type $\theta$ trades $(q^e, \bar{t}^e)$ with buyer $j$ in equilibrium and that $\bar{q} < \bar{q}^e$. Then type $\theta$ strictly prefers $(q^e, \bar{t}^e)$ to $(\bar{q}, \bar{t})$, that is, $\bar{t}^e - \theta q^e > \bar{t} - \theta \bar{q}$. Any buyer $i \neq j$ can deviate by offering a menu consisting of the no-trade contract and of the contract

$$\bar{c}^i(\varepsilon) = (\bar{q} + \varepsilon, \bar{t} + \bar{\theta} v(1 + \varepsilon)),$$

for some strictly positive number $\varepsilon$. Trading $\bar{c}^i(\varepsilon)$ decreases type $\theta$’s payoff by

$$\bar{t}^e - \theta q^e - \bar{t} + \theta \bar{q} - \theta \bar{q}(1 + \varepsilon) - \bar{\theta} \varepsilon$$

compared to what she obtains by trading $(q^e, \bar{t}^e)$ with buyer $j$. Since $\bar{t}^e - \theta q^e > \bar{t} - \theta \bar{q}$, type $\theta$ does not trade $\bar{c}^i(\varepsilon)$ following buyer $i$’s deviation if $\varepsilon$ is close enough to zero. By contrast, trading $\bar{c}^i(\varepsilon)$ allows type $\bar{\theta}$ to increase her payoff by $\bar{\theta} \varepsilon^2$ compared to what she obtains in
equilibrium. Hence type $\bar{\theta}$ trades $\bar{c}(\varepsilon)$ following buyer $i$'s deviation. The payoff for buyer $i$ induced by this deviation is

$$\nu [v(\bar{\theta})(\bar{q} + \varepsilon) - \bar{\theta} - \varepsilon(1 + \varepsilon)] = \nu [v(\bar{\theta}) - \bar{\theta}(1 + \varepsilon)],$$

where use was made of the fact that $\bar{t} = v(\bar{\theta})\bar{q}$ by Step 3. When $\varepsilon < \frac{v(\bar{\theta})}{\theta} - 1$, this payoff is strictly positive, which is impossible by Step 1. Thus type $\theta$ sells a fraction $\bar{q}^e$ of her endowment in any equilibrium, and $(\bar{q}, \bar{t}) = (\bar{q}^e, \bar{t}^e)$ as defined in Proposition 1.

**Step 6** It follows from Steps 4 and 5 that if an equilibrium exists, the contracts that are traded in this equilibrium are $(q^e, t^e)$ and $(\bar{q}^e, \bar{t}^e)$. To conclude the proof, one only needs to determine under which circumstances it is possible to support this allocation in equilibrium.

Suppose first that $\nu > \nu^e$. Any buyer $i$ can deviate by offering a menu consisting of the no-trade contract and of the contract

$$\tilde{c}_i'(\varepsilon) = (1, v(\bar{\theta})\bar{q}^e + \bar{\theta}(1 - \bar{q}^e) + \varepsilon),$$

for some strictly positive number $\varepsilon$. Using the fact that type $\bar{\theta}$ is indifferent between $(q^e, t^e)$ and $(\bar{q}^e, \bar{t}^e)$, one can check that trading $\tilde{c}_i'(\varepsilon)$ allows type $\bar{\theta}$ to increase her payoff by

$$v(\bar{\theta})\bar{q}^e + \bar{\theta}(1 - \bar{q}^e) + \varepsilon - v(\bar{\theta}) = (\bar{\theta} - \bar{\theta})(1 - \bar{q}^e) + \varepsilon$$

compared to what she obtains by trading $(q^e, t^e)$. Hence type $\bar{\theta}$ trades $\tilde{c}_i'(\varepsilon)$ following buyer $i$'s deviation. Similarly, trading $\tilde{c}_i'(\varepsilon)$ allows type $\theta$ to increase her payoff by $\varepsilon$ compared to what she obtains by trading $(\bar{q}^e, \bar{t}^e)$. Hence type $\theta$ trades $\tilde{c}_i'(\varepsilon)$ following buyer $i$’s deviation. Simple computations show that the payoff for buyer $i$ induced by this deviation is

$$E[v(\theta)] - v(\bar{\theta})\bar{q}^e - \bar{\theta}(1 - \bar{q}^e) - \varepsilon = [v(\bar{\theta}) - v(\theta)](\nu - \nu^e) - \varepsilon,$$

which is strictly positive for $\varepsilon$ close enough to zero. Since this is impossible by Step 1, it follows that no equilibrium exists when $\nu > \nu^e$. Suppose then that $\nu \leq \nu^e$. Consider a candidate equilibrium in which each buyer proposes the menu consisting of the no-trade contract and of the contracts $(q^e, t^e)$ and $(\bar{q}^e, \bar{t}^e)$. Then, on the equilibrium path, it is a best response for type $\bar{\theta}$ to trade $(q^e, t^e)$ and for type $\theta$ to trade $(\bar{q}^e, \bar{t}^e)$. By Step 3, this yields each buyer a zero payoff. To verify that this constitutes an equilibrium, one first needs to check that no buyer can strictly increase his payoff by proposing a single contract besides the no-trade contract. By Steps 3, 4 and 5, there is no profitable deviation that would attract only one type of the seller. Moreover, a profitable pooling deviation exists if and only if, given the menus offered in equilibrium, both types of the seller would have a
strict incentive to sell their whole endowment at price \( E[v(\theta)] \). This is the case if and only if \( E[v(\theta)] > v(\bar{\theta})q^e + \bar{\theta}(1 - q^e) \), or equivalently \( \nu > \nu^e \). Thus when \( \nu < \nu^e \), no menu consisting of a single contract besides the no-trade contract can constitute a profitable deviation. To conclude the proof, one only needs to check that no buyer can strictly increase his payoff by offering two contracts besides the no-trade contract, that attract both types of the seller. The maximum payoff that any buyer can achieve in this way is given by

\[
\max_{(q,t,q^e)} \{ \nu[v(\bar{\theta})q - \bar{t}] + (1 - \nu)[v(\bar{\theta})q - \bar{t}] \}
\]

subject to the following incentive and participation constraints:

\[
\begin{align*}
t - \theta q &\geq \bar{t} - \theta \bar{q}, \\
\bar{t} - \theta \bar{q} &\geq t - \theta q, \\
t - \theta q &\geq t^e - \theta q^e, \\
\bar{t} - \theta \bar{q} &\geq \bar{t}^e - \theta \bar{q}^e.
\end{align*}
\]

Note from the incentive constraints that \( q \leq \bar{q} \). It is clear that at least one of the participation constraints must be binding. Suppose first that type \( \theta \)'s participation constraint is binding. If \( q \leq \bar{q}^e \), then the relevant constraint for type \( \bar{\theta} \) is her incentive constraint. It is then optimal to let type \( \bar{\theta} \) be indifferent between \((q^e, t^e)\) and \((q, t)\). Since \( v(\bar{\theta}) > \theta, v(\bar{\theta}) > \bar{\theta} \) and \( q \leq \bar{q}^e \), the maximum payoff that the deviating buyer can achieve in this way is obtained by offering \((q^e, t^e) = (q^e, t^e)\), and is therefore strictly negative. If \( q > \bar{q}^e \), then the relevant constraint for type \( \bar{\theta} \) is her participation constraint. It is then optimal to let type \( \bar{\theta} \) be indifferent between \((q^e, t^e)\) and \((q^e, t^e)\). One cannot have \( q > \bar{q}^e \), for otherwise type \( \theta \) would strictly prefer \((\bar{q}, \bar{t})\) to \((q, t)\). Since \( v(\theta) > \theta, v(\bar{\theta}) > \bar{\theta} \) and \( q \leq \bar{q}^e \), the maximum payoff that the deviating buyer can achieve in this way is obtained by offering the equilibrium contracts \((q^e, t^e)\) and \((q^e, t^e)\). Suppose finally that type \( \theta \)'s participation constraint is binding. If \( \bar{q} \leq \bar{q}^e \), then the relevant constraint for type \( \theta \) is her participation constraint. It is then optimal to let type \( \theta \) be indifferent between \((q, t)\) and \((q^e, t^e)\). Again, since \( v(\theta) > \theta, v(\bar{\theta}) > \bar{\theta} \) and \( \bar{q} \leq \bar{q}^e \), the maximum payoff that the deviating buyer can achieve in this way is obtained by offering the equilibrium contracts \((q^e, t^e)\) and \((q^e, t^e)\). If \( \bar{q} > \bar{q}^e \), then the relevant constraint for type \( \theta \) is her incentive constraint. It is then optimal to let type \( \theta \) be indifferent between \((q, t)\) and \((q, t)\). Simple computations show that the payoff for the deviating buyer is

\[
\{ \nu[v(\bar{\theta}) - \theta] - \bar{\theta} + \theta \} \bar{q} + (1 - \nu)[v(\theta) - \theta]q - t^e + \theta q^e.
\]
Since \( \nu \leq \nu^e \) and \( \Theta > \Theta^e \), this is at most equal to the payoff that the deviating buyer would obtain by offering the equilibrium contracts \((q^e, t^e)\) and \((q^e, \bar{t}^e)\). The result follows. \(\blacksquare\)

**Proof of Lemma 1.** Suppose instead that \( Q < 1 \). Any buyer \( i \) can deviate by offering a menu consisting of the no-trade contract and of two new contracts. The first one is

\[
\phi^i(\varepsilon) = (q^i + 1 - Q, t^i + (\theta + \varepsilon)(1 - Q)),
\]

for some strictly positive number \( \varepsilon \), and is designed to attract type \( \theta \). The second one is

\[
\bar{c}^i(\varepsilon) = (q^i, t^i + \varepsilon^2),
\]

and is designed to attract type \( \bar{\theta} \). The key feature of this deviation is that type \( \bar{\theta} \) can sell her whole endowment by trading \( \phi^i(\varepsilon) \) together with the contracts \( \phi^j \), \( j \neq i \). Since the unit price at which buyer \( i \) offers to purchase the quantity increment \( 1 - Q \) in \( \phi^i(\varepsilon) \) is \( \theta + \varepsilon \), this guarantees her a payoff increase \( (1 - Q)\varepsilon \) compared to what she obtains in equilibrium. When \( \varepsilon \) is close enough to zero, she cannot obtain as much by trading \( \bar{c}^i(\varepsilon) \) instead. Indeed, even if this were to increase her payoff compared to what she obtains in equilibrium, the corresponding increase would at most be \( \varepsilon^2 < (1 - Q)\varepsilon \). Hence type \( \theta \) trades \( \phi^i(\varepsilon) \) following buyer \( i \)'s deviation. Consider now type \( \bar{\theta} \). By trading \( \bar{c}^i(\varepsilon) \) together with the contracts \( \bar{c}^j \), \( j \neq i \), she can increase her payoff by \( \varepsilon^2 \) compared to what she obtains in equilibrium. By trading \( \phi^i(\varepsilon) \) instead, the most she can obtain is her equilibrium payoff, plus the payoff from selling the quantity increment \( 1 - Q \) at unit price \( \theta + \varepsilon \). For \( \varepsilon \) close enough to zero, \( \theta + \varepsilon < \bar{\theta} \) so that this unit price is too low from the point of view of type \( \bar{\theta} \). Hence type \( \bar{\theta} \) trades \( \phi^i(\varepsilon) \) following buyer \( i \)'s deviation. The change in buyer \( i \)'s payoff induced by this deviation is

\[
-\nu\varepsilon^2 + (1 - \nu)[v(\theta) - \bar{\theta} - \varepsilon](1 - Q)
\]

which is strictly positive for \( \varepsilon \) close enough to zero if \( Q < 1 \). Thus \( Q = 1 \), as claimed. \(\blacksquare\)

**Proof of Lemma 2.** Suppose that \( p < \bar{\theta} \) in a separating equilibrium. Any buyer \( i \) can deviate by offering a menu consisting of the no-trade contract and of two new contracts. The first one is

\[
\phi^i(\varepsilon) = (q^i + 1 - Q, t^i + (\theta + \varepsilon)(1 - Q)),
\]

for some strictly positive number \( \varepsilon \), and is designed to attract type \( \theta \). The second one is

\[
\bar{c}^i(\varepsilon) = (q^i, t^i + \varepsilon^2),
\]
and is designed to attract type $\theta$. The key feature of this deviation is that type $\theta$ can sell her whole endowment by trading $c^i(\varepsilon)$ together with the contracts $\bar{c}^j, j \neq i$. Since the unit price at which buyer $i$ offers to purchase the quantity increment $1 - \bar{Q}$ in $c^i(\varepsilon)$ is $p + \varepsilon$, this guarantees her a payoff increase $(1 - \bar{Q})\varepsilon$ compared to what she obtains in equilibrium.

As in the proof of Lemma 1, it is easy to check that when $\varepsilon$ is close enough to zero, she cannot obtain as much by trading $\bar{c}^i(\varepsilon)$ instead. Hence type $\theta$ trades $c^i(\varepsilon)$ following buyer $i$’s deviation. Consider now type $\bar{\theta}$. By trading $\bar{c}^i(\varepsilon)$ together with the contracts $\bar{c}^j, j \neq i$, she can increase her payoff by $\varepsilon^2$ compared to what she obtains in equilibrium. As in the proof of Lemma 1, it is easy to check that when $p + \varepsilon < \bar{\theta}$, she cannot obtain as much by trading $c^i(\varepsilon)$ instead. Hence type $\bar{\theta}$ trades $\bar{c}^i(\varepsilon)$ following buyer $i$’s deviation. The change in buyer $i$’s payoff induced by this deviation is

$$-\nu\varepsilon^2 + (1 - \nu)\{v(\theta)(\bar{q}^i - \theta^i) - t^i + t^i + [v(\theta) - p - \varepsilon](1 - \bar{Q})\},$$

which must at most be zero for any $\varepsilon$ close enough to zero. Since $\bar{Q} = 1$ by Lemma 1, summing over the $i$’s and letting $\varepsilon$ go to zero then yields

$$v(\theta)(\bar{Q} - 1) - \bar{T} + T + n[v(\theta) - p](1 - \bar{Q}) \leq 0,$$

which, from the definition of $p$ and the fact that $\bar{Q} < 1$, implies that

$$(n - 1)[v(\theta) - p] \leq 0.$$

Since $n \geq 2$, it follows that $p \geq v(\theta)$, as claimed. $\blacksquare$

**Proof of Lemma 3.** Suppose that a separating equilibrium exists. Any buyer $i$ can deviate by offering a menu consisting of the no-trade contract and of the contract

$$\bar{c}^i(\varepsilon) = (\bar{q}^i + 1 - \bar{Q}, \bar{t}^i + (\bar{\theta} + \varepsilon)(1 - \bar{Q})),$$

for some strictly positive number $\varepsilon$, that is designed to attract both types of the seller. The key feature of this deviation is that both types can sell their whole endowment by trading $\bar{c}^i(\varepsilon)$ together with the contracts $\bar{c}^j, j \neq i$. Since the unit price at which buyer $i$ offers to purchase the quantity increment $1 - \bar{Q}$ in $\bar{c}^i(\varepsilon)$ is $\bar{\theta} + \varepsilon$, and since $\bar{\theta} \geq p$, this guarantees both types of the seller a payoff increase $(1 - \bar{Q})\varepsilon$ compared to what they obtain in equilibrium. Hence both types trade $\bar{c}^i(\varepsilon)$ following buyer $i$’s deviation. The change in buyer $i$’s payoff induced by this deviation is

$$(E[v(\theta)] - \bar{\theta} - \varepsilon)(1 - \bar{Q}) + (1 - \nu)[v(\theta)(\bar{q}^i - \theta^i) - \bar{t}^i + t^i],$$
which must at most be zero for any \( \varepsilon \). Since \( Q = 1 \) by Lemma 1, summing over the \( i \)'s and letting \( \varepsilon \) go to zero then yields

\[
n\{E[v(\theta)] - \bar{\theta}\} (1 - Q) + (1 - \nu)[v(\theta)(Q - 1) - T + T] \leq 0,
\]

which, from the definition of \( p \) and the fact that \( Q < 1 \), implies that

\[
n\{E[v(\theta)] - \bar{\theta}\} + (1 - \nu)[p - v(\theta)] \leq 0.
\]

Starting from this inequality, two cases must be distinguished. If \( p < \bar{\theta} \), then Lemma 2 applies, and therefore \( p \geq v(\bar{\theta}) \). It then follows that \( E[v(\theta)] \leq \bar{\theta} \). If \( p = \bar{\theta} \), the inequality can be rearranged so as to yield

\[
(n - 1)\{E[v(\theta)] - \bar{\theta}\} + \nu[v(\bar{\theta}) - \bar{\theta}] \leq 0.
\]

Since \( n \geq 2 \) and \( v(\bar{\theta}) > \bar{\theta} \), it follows again that \( E[v(\theta)] \leq \bar{\theta} \), which shows the first part of the result. Consider next some pooling equilibrium, and denote by \((1, T)\) the corresponding aggregate equilibrium allocation. To show that \( T = E[v(\theta)] \), one needs to establish that the buyers’ aggregate payoff is zero in equilibrium. Let \( B^i \) be buyer \( i \)'s equilibrium payoff, which must be at least zero since each buyer always has the option not to trade. Buyer \( i \) can deviate by offering a menu consisting of the no-trade contract and of the contract

\[
\hat{c}^i(\varepsilon) = (1, T + \varepsilon),
\]

for some strictly positive number \( \varepsilon \). It is immediate that both types trade \( \hat{c}^i(\varepsilon) \) following buyer \( i \)'s deviation. The change in payoff for buyer \( i \) induced by this deviation is

\[
E[v(\theta)] - T - \varepsilon - B^i,
\]

which must at most be zero for any \( \varepsilon \). Letting \( \varepsilon \) go to zero yields

\[
B^i \geq E[v(\theta)] - T = \sum_j B^j
\]

where the equality follows from the fact that each type of the seller sells her whole endowment in a pooling equilibrium. Since this inequality holds for each \( i \) and all the \( B^i \)'s are at least zero, they must all in fact be equal to zero. Hence \( T = E[v(\theta)] \), as claimed.

**Proof of Lemma 4.** Suppose first that a pooling equilibrium exists, and denote by \((1, T)\) the aggregate allocation traded by both types in this equilibrium. Then the buyers’ aggregate payoff is \( E[v(\theta)] - T \). One must have \( T - \bar{\theta} \geq 0 \) otherwise type \( \bar{\theta} \) would not trade. Since the
buyers’ aggregate payoff must be at least zero in equilibrium, it follows that \( E[v(\theta)] \geq \bar{\theta} \), which shows the first part of the result. Next, observe that in any separating equilibrium, the buyers’ aggregate payoff is equal to

\[
(1 - \nu)[v(\theta) - T] + \nu[v(\bar{\theta})Q - T] = (1 - \nu)[v(\theta) - p(1 - \bar{Q})] + \nu v(\bar{\theta})Q - T
\]

by definition of \( p \). One shows that \( p \geq v(\theta) \) in any such equilibrium. If \( p < \bar{\theta} \), this follows from Lemma 2. If \( p = \bar{\theta} \), this follows from Lemma 3, which implies that \( \bar{\theta} \geq E[v(\theta)] > v(\theta) \) whenever a separating equilibrium exists. Using this claim along with the fact that \( \bar{T} \geq \bar{\theta}Q \), one obtains that the buyers’ aggregate payoff is at most \( E[v(\theta)] - \theta \bar{Q} \). Since this must be at least zero, one necessarily has \( (\bar{Q}, \bar{T}) = (0, 0) \) whenever \( E[v(\theta)] < \bar{\theta} \). In particular, the buyers’ aggregate payoff \( (1 - \nu)[v(\theta) - p] \) is then equal to zero. It follows that \( p = v(\theta) \) and thus \( \bar{T} = v(\theta) \), which shows the second part of the result.

**Proof of Corollary 1.** In the case of a pooling equilibrium, the result has been established in the proof of Lemma 3. In the case of a separating equilibrium, it has been shown in the proof of Lemma 4 that the buyers’ aggregate payoff is at most \( E[v(\theta)] - \theta \bar{Q} \). As a separating equilibrium exists only if \( E[v(\theta)] \leq \bar{\theta} \), it follows that the buyers’ aggregate payoff is at most zero in any such equilibrium. Since each buyer always has the option not to trade, the result follows.

**Proof of Proposition 2.** Assume first that \( E[v(\theta)] \geq \bar{\theta} \), so that \( p^* = E[v(\theta)] \). The proof goes through a series of steps.

**Step 1** Given the menus offered, any best response of the seller leads to an aggregate trade \((1, E[v(\theta)])\) irrespective of her type. Assuming that each buyer trades the same quantity with both types of the seller, all buyers obtain a zero payoff.

**Step 2** No buyer can profitably deviate in such a way that both types of the seller trade the same contract \((q, t)\) with him. Indeed, such a deviation is profitable only if \( E[v(\theta)]q > t \). However, given the menus offered by the other buyers, the seller always has the option to trade quantity \( q \) at unit price \( E[v(\theta)] \). She would therefore be strictly worse off trading the contract \((q, t)\) no matter her type. Such a deviation is thus infeasible.

**Step 3** No buyer can deviate in such a way that he obtains a strictly positive payoff from trading with type \( \theta \). Indeed, an additional contract \((q, t)\) attracts type \( \bar{\theta} \) only if \( t \geq E[v(\theta)]q \), since she has the option to trade any quantity at unit price \( E[v(\theta)] \). The corresponding payoff for the deviating buyer is then at most \( v(\theta) - E[v(\theta)]q \) which is at most zero.
Step 4 By Step 3, a profitable deviation must attract type $\bar{\theta}$. An additional contract $(\bar{q}, \bar{t})$ attracts type $\bar{\theta}$ only if $\bar{t} \geq \mathbb{E}[v(\theta)]\bar{q}$, since she has the option to trade any quantity at unit price $\mathbb{E}[v(\theta)]$. However, type $\theta$ can then also weakly increase her payoff by mimicking type $\bar{\theta}$’s behavior. One can therefore construct the seller’s strategy in such a way that it is impossible for any buyer to deviate by trading with type $\bar{\theta}$ only.

Step 5 By Steps 3 and 4, a profitable deviation must involve trading with both types. Whatever the contract traded by the seller with the deviating buyer, and no matter her type, she can sell to the other buyers the remaining fraction of her endowment at unit price $\mathbb{E}[v(\theta)]$. Hence each type of the seller faces the same problem, namely to optimally use the deviating buyer’s and the other buyers’ offers to sell her whole endowment at the maximum price. One can therefore construct the seller’s strategy in such a way that each type selects the same contract from the deviating buyer’s menu. By Step 2, this makes such a deviation non profitable. Hence the result.

Assume next that $\mathbb{E}[v(\theta)] < \bar{\theta}$, so that $p^* = v(\theta)$. Again, the proof goes through a series of steps.

Step 1 Given the menus offered, any best response of the seller leads to aggregate trades $(1, v(\theta))$ for type $\theta$ and $(0, 0)$ for type $\bar{\theta}$, and all buyers obtain a zero payoff.

Step 2 No buyer can profitably deviate in such a way that both types of the seller trade the same contract $(q, t)$ with him. Indeed, such a deviation is profitable only if $\mathbb{E}[v(\theta)]q > t$. Since $\bar{\theta} > \mathbb{E}[v(\theta)]$, this however implies that $t - \bar{\theta}q < 0$, so that type $\bar{\theta}$ would be strictly worse off trading the contract $(q, t)$. Such a deviation is thus infeasible.

Step 3 No buyer can deviate in such a way that he obtains a strictly positive payoff from trading with type $\theta$. Indeed, an additional contract $(\bar{q}, \bar{t})$ attracts type $\theta$ only if $\bar{t} \geq v(\theta)\bar{q}$, since she always has the option to trade quantity $\bar{q}$ at unit price $v(\theta)$. The corresponding payoff for the deviating buyer is then at most zero.

Step 4 By Step 3, a profitable deviation must attract type $\bar{\theta}$. An additional contract $(\bar{q}, \bar{t})$ attracts type $\bar{\theta}$ only if $\bar{t} \geq \bar{\theta}\bar{q}$. However, since $\bar{\theta} > \mathbb{E}[v(\theta)] > v(\theta)$, type $\theta$ can then strictly increase her payoff by trading the contract $(\bar{q}, \bar{t})$ and selling to the other buyers the remaining fraction of her endowment at unit price $v(\theta)$. It is thus impossible for any buyer to deviate by trading with type $\bar{\theta}$ only.

Step 5 By Steps 3 and 4, a profitable deviation must involve trading with both types.
Given the menus offered, the most profitable deviations involve trading some quantity $q$ at unit price $\theta$, and trading a quantity 1 at unit price $\theta q + v(\theta)(1 - q)$ with type $\theta$. By construction, type $\theta$ is indifferent between trading the contract $(1, \theta q + v(\theta)(1 - q))$ and trading the contract $(q, \theta q)$ while selling to the other buyers the remaining fraction of her endowment at unit price $v(\theta)$. As for type $\theta$, she is indifferent between trading the contract $(q, \theta q)$ and not trading at all. The corresponding payoff for the deviating buyer is then

$$\nu[q(\theta) - \theta]q + (1 - \nu)v(\theta) - \theta q - v(\theta)(1 - q) = \{E[v(\theta)] - \theta\}q,$$

which is at most zero when $E[v(\theta)] < \theta$. Hence the result.

**Proof of Proposition 3.** Assume first that $E[v(\theta)] > \theta$, so that $p^* = E[v(\theta)]$. Suppose an equilibrium exists in which some buyer $i$ offers a contract $c^i = (q^i, t^i)$ at unit price $\frac{v^i}{q^i} > E[v(\theta)]$. Notice that one must have $E[v(\theta)] - t^i \geq \theta(1 - q^i)$ otherwise $c^i$ would give type $\theta$ more than her equilibrium payoff. Similarly, one must have $q^i < 1$ otherwise $c^i$ would give both types more than their equilibrium payoff. Any other buyer $j$ could offer a menu consisting of the no-trade contract and of the contract

$$c^j(\varepsilon) = (1 - q^i, E[v(\theta)] - t^i + \varepsilon),$$

with $0 < \varepsilon < t^i - q^iE[v(\theta)]$. If both $c^j$ and $c^j(\varepsilon)$ were available, both types of the seller would sell their whole endowment at price $E[v(\theta)] + \varepsilon$ by trading $c^i$ with buyer $i$ and $c^j(\varepsilon)$ with buyer $j$, thereby increasing their payoff by $\varepsilon$ compared to what they obtain in equilibrium. Buyer $j$’s equilibrium payoff is thus at least

$$E[v(\theta)](1 - q^i) - \{E[v(\theta)] - t^i + \varepsilon\} = t^i - q^iE[v(\theta)] - \varepsilon > 0,$$

which is impossible since each buyer’s payoff is zero in any equilibrium by Corollary 1. Hence no contract can be issued at a price strictly above $E[v(\theta)]$. The result follows.

Assume next that $E[v(\theta)] < \theta$, so that $p^* = v(\theta)$. Suppose an equilibrium exists in which some buyer $i$ offers a contract $c^i = (q^i, t^i)$ at unit price $\frac{v^i}{q^i} > v(\theta)$. Notice that one must have $t^i \leq \theta q^i$ otherwise $c^i$ would give type $\theta$ more than her equilibrium payoff. Similarly, one must have $v(\theta) - t^i \geq \theta(1 - q^i)$ and $q^i < 1$ otherwise $c^i$ would give type $\theta$ more than her equilibrium payoff. Any other buyer $j$ could offer a menu consisting of the no-trade contract and of the contract

$$c^j(\varepsilon) = (1 - q^i, v(\theta) - t^i + \varepsilon),$$

where $0 < \varepsilon < \min\{t^i - q^i v(\theta), \theta - v(\theta)\}$. If both $c^i$ and $c^j(\varepsilon)$ were available, type $\theta$ would
sell her whole endowment at price \( v(\theta) + \varepsilon \) by trading \( c_i^j \) with buyer \( i \) and \( c_i^j(\varepsilon) \) with buyer \( j \), thereby increasing her payoff by \( \varepsilon \) compared to what she obtains in equilibrium. Moreover, since \( v(\theta) + \varepsilon < \theta \), type \( \theta \) would strictly lose from trading \( c_i^j(\varepsilon) \) with buyer \( j \). Buyer \( j \)’s equilibrium payoff is thus at least

\[
(1 - \nu)[v(\theta)(1 - q^i) - [v(\theta) - t^i + \varepsilon]] = (1 - \nu)[t^i - q^i v(\theta) - \varepsilon] > 0,
\]

which is impossible since each buyer’s payoff is zero in any equilibrium by Corollary 1. Hence no contract can be issued at a price strictly above \( v(\theta) \). The result follows.

**Proof of Corollary 2.** Assume first that \( E[v(\theta)] > \theta \), so that \( p^* = E[v(\theta)] \). From Proposition 3, no contract is issued, and a fortiori traded, at a unit price strictly above \( E[v(\theta)] \) in equilibrium. Suppose now that a contract with unit price strictly below \( E[v(\theta)] \) is traded in equilibrium. Then, since the aggregate allocation traded by both types is \((1, E[v(\theta)])\), a contract with unit price strictly above \( E[v(\theta)] \) must be traded in equilibrium, a contradiction. Hence the result.

Assume next that \( E[v(\theta)] < \theta \), so that \( p^* = v(\theta) \). From Proposition 3, no contract is issued, and a fortiori traded, at a unit price strictly above \( v(\theta) \) in equilibrium. Suppose now that a contract with unit price strictly below \( v(\theta) \) is traded in equilibrium. Then, since the aggregate allocation traded by type \( \theta \) is \((1, v(\theta))\), a contract with unit price strictly above \( v(\theta) \) must be traded in equilibrium, a contradiction. Hence the result. ■

**Proof of Proposition 4.** Fix some equilibrium with menu offers \((C^1, \ldots, C^m)\), and let

\[
\mathfrak{A}^{-i} = \left\{ \sum_{j \neq i} (q^j, t^j) : (q^j, t^j) \in C^j \text{ for all } j \neq i \text{ and } \sum_{j \neq i} q^j \leq 1 \right\}
\]

be the set of aggregate allocations that remain available if buyer \( i \) withdraws his menu offer \( C^i \). By construction, \( \mathfrak{A}^{-i} \) is a compact set. One must show that \((1, p^*) \in \mathfrak{A}^{-i}\).

Assume first that \( E[v(\theta)] > \theta \), so that \( p^* = E[v(\theta)] \). Suppose the aggregate allocation \((1, E[v(\theta)])\) traded by both types does not belong to \( \mathfrak{A}^{-i} \). Since \( \mathfrak{A}^{-i} \) is compact, there exists some open set of \([0, 1] \times \mathbb{R}_+\) that contains \((1, E[v(\theta)])\) and that does not intersect \( \mathfrak{A}^{-i} \). Moreover, any allocation \((Q^{-i}, T^{-i}) \in \mathfrak{A}^{-i}\) is such that \( T^{-i} \leq E[v(\theta)]Q^{-i} \) by Proposition 3. Since \( E[v(\theta)] > \theta \), this implies that \( \mathfrak{A}^{-i} \) does not intersect the set of allocations that are weakly preferred by both types to \((1, E[v(\theta)])\). By continuity of the seller’s preferences, it follows that there exists some strictly positive number \( \varepsilon \) such that the contract \((1, E[v(\theta)] - \varepsilon)\) is strictly preferred by each type to any allocation in \( \mathfrak{A}^{-i} \). Thus, if this contract were
available, both types would trade it. This implies that buyer \( i \)'s equilibrium payoff is at least \( \varepsilon \), which is impossible since each buyer's payoff is zero in any equilibrium by Corollary 1. Hence \( (1, E[v(\theta)]) \in A^{-i} \). The result follows.

Assume next that \( E[v(\theta)] < \bar{\theta} \), so that \( p^* = v(\theta) \). Suppose the aggregate allocation \( (1, v(\theta)) \) traded by type \( \theta \) does not belong to \( A^{-i} \). Since \( A^{-i} \) is compact, there exists an open set of \([0, 1] \times \mathbb{R}_+\) that contains \((1, v(\theta))\) and that does not intersect \( A^{-i} \). Moreover, any allocation \((Q^{-i}, T^{-i}) \in A^{-i}\) is such that \( T^{-i} \leq v(\theta)Q^{-i} \) by Proposition 3. Since \( \theta < v(\theta) \), this implies that \( A^{-i} \) does not intersect the set of allocations that are weakly preferred by type \( \theta \) to \((1, v(\theta))\). Since the latter set is closed and \( A^{-i} \) is compact, it follows that there exists a contract \((\bar{q}^i, \bar{t}^i)\) with unit price \( \frac{\lambda}{\bar{q}^i} \in (\bar{\theta}, v(\theta)) \) such that the allocation \((1, v(\theta))\) is strictly preferred by type \( \theta \) to any allocation obtained by trading the contract \((\bar{q}^i, \bar{t}^i)\) together with some allocation in \( A^{-i} \).\(^{21}\) Moreover, since \( \frac{\lambda}{\bar{q}^i} > \bar{\theta} \), the contract \((\bar{q}^i, \bar{t}^i)\) guarantees a strictly positive payoff to type \( \bar{\theta} \). Thus, if both \((1, v(\theta))\) and \((\bar{q}^i, \bar{t}^i)\) were available, type \( \theta \) would trade \((1, \bar{\theta})\) and type \( \bar{\theta} \) would trade \((\bar{q}^i, \bar{t}^i)\). This implies that buyer \( i \)'s equilibrium payoff is at least \( v[v(\bar{\theta})\bar{q}^i - \bar{t}^i] > 0 \), which is impossible since each buyer’s payoff is zero in any equilibrium by Corollary 1. Hence \((1, v(\theta)) \in A^{-i}\). The result follows. \( \blacksquare \)

**Proof of Proposition 5.** Fix some equilibrium and some buyer \( i \), and define the set \( A^{-i} \) as in the proof of Proposition 4. One must show that \( A^{-i} \) is infinite. Define

\[
z^{-i}(\theta, Q) = \max \{ T^{-i} - \theta Q^{-i} : (Q^{-i}, T^{-i}) \in A^{-i} \text{ and } Q^{-i} \leq Q \}
\]

to be the highest payoff that a seller of type \( \theta \) can get from trading with buyers \( j \neq i \), when her remaining stock is \( Q \). Notice that \( z^{-i}(\theta, Q) \) is positive and increasing in \( Q \). Observe that

\[
T^{-i} - \bar{\theta} Q^{-i} = T^{-i} - \theta Q^{-i} + (\theta - \bar{\theta}) Q^{-i} \geq T^{-i} - \theta Q^{-i} + (\theta - \bar{\theta}) Q
\]

as long as \( Q^{-i} \leq Q \). Taking maximums on both sides of this inequality yields

\[
z^{-i}(\bar{\theta}, Q) \geq z^{-i}(\theta, Q) + (\theta - \bar{\theta}) Q
\]

for all \( Q \in [0, 1] \). Now, let \( U(\theta) \) be the equilibrium payoff of type \( \theta \). It follows from Proposition 4 that this payoff remains available to type \( \theta \) if buyer \( i \) withdraws his menu offer. Suppose that buyer \( i \) deviates by offering a menu consisting of the no-trade contract and of a contract \((\bar{q}^i, \bar{t}^i)\) that is designed to attract only type \( \bar{\theta} \). To ensure that this is so, one

\(^{21}\)This follows directly from the fact that if \( K \) is compact and \( F \) is closed in some normed vector space \( X \), and if \( K \cap F = \emptyset \), then for any vector \( u \) in \( X \), \((K + \lambda u) \cap F = \emptyset \) for any sufficiently small scalar \( \lambda \).
imposes the following incentive compatibility constraints:

\[ U(\theta) > \bar{t} - \theta q + z^{-i}(\theta, 1 - \bar{q}), \]

\[ \bar{t} - \theta q + z^{-i}(\bar{\theta}, 1 - \bar{q}) > U(\bar{\theta}). \]

Clearly these constraints together require that

\[ \theta q - z^{-i}(\theta, 1 - \bar{q}) - [v(\bar{\theta}) - \bar{q}] \leq U(\bar{\theta}) - z^{-i}(\bar{\theta}, 1 - \bar{q}). \]

(4)

The resulting payoff for buyer \( i \) is then \( v(\bar{\theta}) q - \bar{t} \), which must at most be zero by Corollary 1. Since \( \bar{t} \) can be as close as one wishes to \( \theta q - z^{-i}(\theta, 1 - \bar{q}) + U(\bar{\theta}) \), one thus obtains the following implication: if \( q \) satisfies (4), then

\[ [v(\bar{\theta}) - \bar{q}] \leq U(\bar{\theta}) - z^{-i}(\bar{\theta}, 1 - \bar{q}). \]

(5)

Two cases must now be distinguished.

Assume first that \( \mathbb{E}[v(\theta)] > \bar{\theta} \), so that \( U(\bar{\theta}) = \mathbb{E}[v(\theta)] - \bar{\theta} \) and \( U(\theta) = \mathbb{E}[v(\theta)] - \theta \) by Lemma 3. Then (5) is false if and only if

\[ z^{-i}(\bar{\theta}, 1 - \bar{q}) > \mathbb{E}[v(\theta)] - \bar{\theta} - [v(\bar{\theta}) - \bar{\theta}] \frac{1}{\bar{q}'}. \]

(6)

Define \( \bar{q}^* = \frac{\mathbb{E}[v(\theta)] - \bar{\theta}}{v(\bar{\theta}) - \bar{\theta}} \), and observe that \( 0 < \bar{q}^* < 1 \). For \( \bar{q} > \bar{q}^* \), the right-hand side of (6) is negative, and thus (6) holds. Hence (5) is false, and therefore (4) is false as well:

\[ z^{-i}(\bar{\theta}, 1 - \bar{q}) \leq z^{-i}(\theta, 1 - \bar{q}) + (\theta - \bar{\theta})(1 - \bar{q}). \]

Letting \( Q = 1 - \bar{q} \) and combining this inequality with (3), one obtains that

\[ z^{-i}(\bar{\theta}, Q) = z^{-i}(\theta, Q) + (\theta - \bar{\theta})Q \]

(7)

for all \( Q < 1 - \bar{q}^* \). One now shows that (7) implies that for any such \( Q \), and for any solution \((Q^{-i}(\bar{\theta}, Q), T^{-i}(\bar{\theta}, Q))\) to the maximization problem that defines \( z^{-i}(\theta, Q) \), one has \( Q^{-i}(\theta, Q) = Q \). To see this, observe that the trade \((Q^{-i}(\bar{\theta}, Q), T^{-i}(\bar{\theta}, Q))\) is also feasible for type \( \bar{\theta} \) in the maximization problem that defines \( z^{-i}(\bar{\theta}, Q) \). Thus one must have

\[ z^{-i}(\bar{\theta}, Q) \geq T^{-i}(\bar{\theta}, Q) - \bar{\theta}Q^{-i}(\bar{\theta}, Q) = z^{-i}(\bar{\theta}, Q) + (\theta - \bar{\theta})Q^{-i}(\theta, Q). \]

(8)

The inequality in (8) cannot be strict, for otherwise \( z^{-i}(\bar{\theta}, Q) > z^{-i}(\bar{\theta}, Q) + (\theta - \bar{\theta})Q \) as \( Q^{-i}(\theta, Q) \leq Q \), which would contradict (7). It follows that (8) holds as an equality, which implies that \( Q^{-i}(\theta, Q) = Q \) by (7). Since this equality is true for all \( Q \in [0, 1 - \bar{q}^*] \), it follows
from the definition of $z^{-i}(\theta, \cdot)$ that there exists a continuum of distinct points in $\mathcal{A}^{-i}$. Hence the result.

Assume next that $E[v(\theta)] < \bar{\theta}$, so that $U(\theta) = v(\theta) - \theta$, $U(\bar{\theta}) = 0$ and $z^{-i}(\bar{\theta}, \cdot) = 0$ by Lemma 4. Then the right-hand side of (5) is zero, while the left-hand side is strictly positive as long as $\bar{q}$ is strictly positive. Therefore (4) cannot hold for any such $\bar{q}$, which implies that

$$v(\theta) - \theta - (\bar{\theta} - \theta)\bar{q} \leq z^{-i}(\theta, 1 - \bar{q})$$

for all $\bar{q} \in (0, 1]$. Moreover, by Proposition 3, no contract can be issued at a price strictly above $p^* = v(\theta)$. Thus

$$z^{-i}(\theta, 1 - \bar{q}) \leq [v(\theta) - \bar{\theta}](1 - \bar{q})$$

for all $\bar{q} \in (0, 1]$. Letting $Q = 1 - \bar{q}$ and combining these two inequalities, one obtains the following lower and upper bounds for $z^{-i}(\theta, Q)$:

$$v(\theta) - \bar{\theta} + (\bar{\theta} - \theta)Q \leq z^{-i}(\theta, Q) \leq [v(\theta) - \bar{\theta}]Q$$

for all $Q \in [0, 1)$. Since these bounds are strictly increasing in $Q$ and coincide at $Q = 1$, it follows from the definition of $z^{-i}(\theta, \cdot)$ that there exists a sequence in $\mathcal{A}^{-i}$ composed of distinct points that converges to $(1, v(\theta))$. Hence the result. ■

Proof of Proposition 6. (i) The proof goes through a series of steps.

Step 1 Given the menus offered, any best response of the seller leads to an aggregate trade $(1, E[v(\theta)])$ irrespective of her type. Since $\phi < E[v(\theta)]$, it is optimal for each type of the seller to trade her whole endowment with a single buyer. Assuming that each type of the seller trades with the same buyer, all buyers obtain a zero payoff. Note also that if any buyer withdraws his menu offer, the most the seller can achieve by trading with the other buyers consists in trading with a single buyer.

Step 2 No buyer can profitably deviate in such a way that both types of the seller trade the same contract $(q, t)$ with him. Indeed, such a deviation is profitable only if $E[v(\theta)]q > t$. Since $\phi < E[v(\theta)]$, the highest payoff the seller can achieve by purchasing the contract $(q, t)$ together with some contract in the menu offered by the other buyers is less than the payoff from trading the contract $(1, E[v(\theta)])$, which remains available at the deviation stage. She would therefore be strictly worse off trading the contract $(q, t)$ no matter her type. Such a deviation is thus infeasible.
Step 3 No buyer can deviate in such a way that he obtains a strictly positive payoff from trading with type $\theta$. Indeed, trading an additional contract $(q, t)$ with type $\theta$ is profitable only if $v(\theta)q > t$. The same argument as in Step 2 then shows that type $\theta$ would be strictly worse off trading the contract $(q, t)$ rather than the contract $(1, E[v(\theta)])$, which remains available at the deviation stage. Such a deviation is thus infeasible.

Step 4 By Step 3, a profitable deviation must attract type $\bar{\theta}$. An additional contract $(\bar{q}, \bar{t})$ that is profitable when traded with type $\bar{\theta}$ attracts her only if $\bar{t} + \phi(1 - \bar{q}) \geq E[v(\theta)]$, that is, only if she can weakly increase her payoff by trading the contract $(\bar{q}, \bar{t})$ and selling to the other buyers the remaining fraction of her endowment at unit price $\phi$. That this is feasible follows from the fact that, when $\bar{t} + \phi(1 - \bar{q}) \geq E[v(\theta)]$ and $v(\theta)\bar{q} > \bar{t}$, the quantity $1 - \bar{q}$ is less than the maximal quantity $\frac{v(\theta) - E[v(\theta)]}{v(\theta) - \phi}$ that can be traded at unit price $\phi$ with the other buyers. Moreover, the fact that $\phi \geq \bar{\theta}$ guarantees that it is indeed optimal for type $\bar{\theta}$ to behave in this way at the deviation stage. However, type $\theta$ can then also weakly increase her payoff by mimicking type $\bar{\theta}$’s behavior. One can therefore construct the seller’s strategy in such a way that it is impossible for any buyer to deviate by trading with type $\theta$ only.

Step 5 By Steps 3 and 4, a profitable deviation must involve trading with both types. Whatever the contract traded by the seller with the deviating buyer, and no matter her type, she will sell to the other buyers the remaining fraction of her endowment at unit price $\phi$. Hence, each type of the seller faces the same problem, namely to use optimally the deviating buyer’s and the other buyers’ offers to sell her whole endowment at the maximum price. One can therefore construct the seller’s strategy in such a way that each type selects the same contract from the deviating buyer’s menu. By Step 2, this makes such a deviation non-profitable. The result follows.

(ii) The proof goes through a series of steps.

Step 1 Given the menus offered, any best response of the seller leads to an aggregate trade $(1, v(\theta))$ for type $\theta$ and $(0, 0)$ for type $\bar{\theta}$. Since each buyer is not ready to pay anything for quantities up to $\frac{\psi - \theta}{\psi}$ and offers to purchase each additional unit at a constant marginal price $\psi$ above this level, it is optimal for type $\bar{\theta}$ to trade her whole endowment with a single buyer, and all buyers obtain a zero payoff. Note also that if any buyer withdraws his menu offer, the most the seller can achieve by trading with the other buyers consists in trading with a single buyer.

Step 2 No buyer can profitably deviate in such a way that both types of the seller trade
the same contract \((q,t)\) with him. This can be shown as in Step 2 of the first part of the proof of Proposition 2.

**Step 3** No buyer can deviate in such a way that he obtains a strictly positive payoff from trading with type \(\theta\). Indeed, trading an additional contract \((q,t)\) with type \(\theta\) is profitable only if \(v(\theta)q > t\). Since \(\psi > v(\theta)\), the highest payoff type \(\theta\) can achieve by purchasing the contract \((q,t)\) together with some contract in the menu offered by the other buyers is less than the payoff from trading the contract \((1,v(\theta))\), which remains available at the deviation stage. She would therefore be strictly worse off trading the contract \((q,t)\). Such a deviation is thus infeasible.

**Step 4** By Step 3, a profitable deviation must attract type \(\theta\). An additional contract \((q,t)\) attracts type \(\theta\) only if \(t \geq \theta q\). Two cases must be distinguished. If \(q \leq v(\theta)\psi\), then type \(\theta\) can trade the contract \((q,t)\) and sell to some other buyer the remaining fraction of her endowment at price \(\psi(1-q) - \psi + v(\theta)\). The price at which she can sell her whole endowment is therefore at least \((\theta - \psi)q + v(\theta)\), which is strictly higher than the price \(\theta\) that she obtains in equilibrium since \(\theta > v(\theta)\). If \(q > v(\theta)\psi\), then by trading the contract \((q,t)\), type \(\theta\) obtains at least a payoff \(\frac{\theta - E[v(\theta)]}{1-\nu}\), which, since \(\theta > \psi > v(\theta)\), is more than her equilibrium payoff \(v(\theta) - \theta\). Thus type \(\theta\) can always strictly increase her payoff by trading the contract \((q,t)\). It is therefore impossible for any buyer to deviate by trading with type \(\theta\) only.

**Step 5.** By Steps 3 and 4, a profitable deviation must involve trading with both types. Given the menus offered, the most profitable deviations lead to trading some quantity \(q \leq \frac{v(\theta)}{\psi}\) at unit price \(\theta\) with type \(\theta\), and trading a quantity 1 at unit price \(\theta q + v(\theta) - \psi q\) with type \(\theta\). By construction, type \(\theta\) is indifferent between trading the contract \((1,\theta q + v(\theta) - \psi q)\) and trading the contract \((q,\theta q)\) while selling to the other buyers the remaining fraction of her endowment at price \(\psi(1-q) - \psi + v(\theta)\). As for type \(\theta\), she is indifferent between trading the contract \((q,\theta q)\) and not trading at all. The corresponding payoff for the deviating buyer is then

\[\nu[v(\theta) - \theta q] + (1-\nu)\{v(\theta) - [\theta q + v(\theta) - \psi q]\} = [\nu v(\theta) + (1-\nu)\psi - \theta q],\]

which is at most zero since \(\psi \leq v(\theta) + \frac{\theta - E[v(\theta)]}{1-\nu}\). The result follows.

**Proof of Lemma 5.** For further reference, one solves here a slightly more general problem, that is parameterized by \((\theta_0,\theta_1,Q_0,Q_1)\), where \(\theta \leq \theta_0 \leq \theta_1 \leq \theta\) and \(0 \leq Q_1 \leq Q_0 \leq 1\). This
problem consists in maximizing

\[
\int_{\bar{\theta}}^{\theta_1} \left[ v(\theta)Q(\theta) - T(\theta) \right] dF(\theta),
\]

subject to the seller’s incentive compatibility and individual rationality constraints

\[
T(\theta) - \theta Q(\theta) \geq T(\theta') - \theta Q(\theta'),
\]

\[
T(\theta) - \theta Q(\theta) \geq 0,
\]

for all \((\theta, \theta') \in [\bar{\theta}, \theta_1]^2\), and to the two additional constraints that

\[
Q(\theta) = Q_0
\]

for all \(\theta \in [\bar{\theta}, \theta_0]\), and that

\[
Q(\theta) \geq Q_1
\]

for all \(\theta \in [\bar{\theta}, \theta_1]\). The monopsony problem corresponds to \((\theta_0, \theta_1, Q_0, Q_1) = (\bar{\theta}, \bar{\theta}, 1, 0)\). Letting \(U(\theta) = T(\theta) - \theta Q(\theta)\), standard techniques imply that the incentive compatibility constraints are equivalent to the two conditions that \(U(\theta) = \int_{\theta}^{\theta_1} Q(\theta') d\theta + U(\theta_1)\) for all \(\theta \in [\bar{\theta}, \theta_1]\) and that the function \(Q\) be decreasing over \([\bar{\theta}, \theta_1]\) (Rochet (1985)). Clearly, the participation constraint of the seller must be binding at \(\theta_1\), \(U(\theta_1) = 0\). Substituting for \(U(\theta)\) in the objective function and integrating by parts, the problem reduces to maximizing

\[
\int_{\bar{\theta}}^{\theta_1} [v(\theta) - \theta]Q(\theta) dF(\theta) - \int_{\bar{\theta}}^{\theta_1} F(\theta)Q(\theta) d\theta
\]

subject to the constraint that \(Q\) be decreasing, and to the two additional constraints stated above. Observe that, for each \(p \in [\bar{\theta}, \theta_1]\),

\[
\int_{\bar{\theta}}^{p} [v(\theta) - \theta] dF(\theta) - \int_{\bar{\theta}}^{p} F(\theta) d\theta = w(p),
\]

with \(w(p)\) defined as in (2). Thus the objective in (9) can be more compactly rewritten as

\[
\int_{\bar{\theta}}^{\theta_1} Q(\theta) dw(\theta),
\]

which, from the integration by parts formula for functions of bounded variation (Dellacherie and Meyer (1982, Chapter VI, Theorem 90)), is in turn equal to

\[
Q_1 w(\theta_1) + \int_{\bar{\theta}}^{\theta_1} w(\theta) d(Q_0 - Q_1)(\theta),
\]

(10)
where $Q^+$ is the right-continuous regularization of $Q$ such that $Q^+(\theta_1) = Q_1$.\(^2^2\) Since $Q$ is decreasing and bounded below by $Q_1$, $d(Q_0 - Q^+)$ is a positive measure of mass $Q_0 - Q_1$ over $[\theta, \theta_1]$. Moreover, since $Q = Q_0$ over $[\theta, \theta_0]$, $d(Q_0 - Q^+)$ does not charge $[\theta, \theta_0)$. Thus the maximum in (10) is reached by putting all the weight of the measure $d(Q_0 - Q^+)$ on a maximum point of the function $w$ over $[\theta_0, \theta_1]$, yielding a payoff

$$Q_1 w(\theta_1) + (Q_0 - Q_1) \sup_{\theta \in [\theta_0, \theta_1]} \{w(\theta)\}. \tag{11}$$

In the case of the monopsony, $(\theta_0, \theta_1, Q_0, Q_1) = (\theta, \bar{\theta}, 1, 0)$. It then follows from (11) and from the definition of $p^m$ that the maximum payoff that the monopsony can obtain is $w^m = w(p^m)$. Hence the result. \hfill \blacksquare

**Proof of Proposition 7.** Consider a conservative equilibrium in which each type $\theta$ sells a quantity $Q(\theta)$ and obtains a payoff $U(\theta)$. Define $B^i(\theta)$ as the payoff obtained by buyer $i$ from trading with type $\theta$. For the purpose of this proof, it is convenient to extend these functions to $(\bar{\theta}, \infty)$, which raises no difficulty.\(^2^3\) Consistent with this, a type hereafter refers to an arbitrary element of $[\theta, \infty)$. Note that $Q(\theta)$ goes to 0 as $\theta$ goes to infinity. Observe that $U(\theta) = \int_\theta^{\bar{\theta}} Q(\vartheta) d\vartheta + U(\bar{\theta})$ by the envelope theorem; thus $U$ is affine over an interval of types if and only if $Q$ is constant over the interior of this interval; moreover $U$ is convex as $Q$ is decreasing by incentive compatibility. The following result will be used repeatedly.

**Lemma 6** Suppose that $U$ is not affine over $[\theta_a, \theta_b]$, where $\theta \leq \theta_a < \theta_b$. Define

$$q_0 = \frac{U(\theta_a) - U(\theta_b)}{\theta_b - \theta_a} \text{ and } t_0 = \frac{\theta_b U(\theta_a) - \theta_a U(\theta_b)}{\theta_b - \theta_a}. \tag{12}$$

Then one must have

$$n \int_{\theta_a}^{\theta_b} [v(\theta)q_0 - t_0] dF(\theta) \leq \int_{\theta_a}^{\theta_b} [(v(\theta) - \theta)Q(\theta) - U(\theta)] dF(\theta). \tag{13}$$

**Proof.** Since $U'(\theta) = -Q(\theta)$ except at most for a countable number of types, $q_0$ is an average of the quantities sold by types in $[\theta_a, \theta_b]$. Because $U$ is not affine over this interval, it must be that these quantities take at least two different values. Therefore $Q(\theta_b) < q_0 < Q(\theta_a)$. Any

\(^2^2\)To apply the integration by parts formula, observe that one can assume without loss of generality that $Q$ is left-continuous.

\(^2^3\)That is, for each $\theta \in (\bar{\theta}, \infty)$, simply set $U(\theta) = \sup \{t^i - \theta q^i : (q^i, t^i) \in C^i \text{ for some } i \}$ and arbitrarily select some $Q(\theta)$ in $\arg \max \{t^i - \theta q^i : (q^i, t^i) \in C^i \text{ for some } i \}$. As for the $B^i(\theta)$’s, it is immaterial how they are defined outside of the support of the seller’s type distribution. For consistency we shall nevertheless assume that they add up to $[v(\theta) - \theta]Q(\theta) - U(\theta)$, as for types belonging to the support of the seller’s type distribution.
buyer $i$ can deviate by adding to his equilibrium menu the contract $(q_0, t_0)$. By definition of $q_0$ and $t_0$ one has
\[ U(\theta_a) = t_0 - \theta_a q_0 \quad \text{and} \quad U(\theta_b) = t_0 - \theta_b q_0, \tag{14} \]
so that types $\theta_a$ and $\theta_b$ are indifferent to this new offer. Consider a type $\theta \in (\theta_a, \theta_b)$. If this type were also indifferent, then the convex function $U$ would have to be equal to the affine mapping $\theta \mapsto t_0 - \theta q_0$ over the interval $[\theta_a, \theta_b]$, contradicting the assumption. Thus type $\theta$ cannot be indifferent, and because $U$ is convex it must be that $U(\theta) < t_0 - \theta q_0$. Therefore all types in $(\theta_a, \theta_b)$ are strictly better off trading the contract $(q_0, t_0)$. Consider now types $\theta > \theta_b$. Convexity of $U$ implies that for these types $U(\theta) \geq U(\theta_b) - Q(\theta_b)(\theta - \theta_b)$, and using (14) along with the fact that $q_0 > Q(\theta_b)$ yields
\[ U(\theta) \geq t_0 - \theta q_0 + [q_0 - Q(\theta_b)](\theta - \theta_b) > t_0 - \theta q_0 \]
for all $\theta > \theta_b$. Therefore all types $\theta > \theta_b$ are strictly worse off trading the contract $(q_0, t_0)$. As the equilibrium under scrutiny is assumed to be conservative, such types do not change their behavior following buyer $i$'s deviation. The same properties can similarly be established for all types $\theta < \theta_a$. The change in buyer $i$'s payoff induced by this deviation is thus
\[ \int_{\theta_a}^{\theta_b} [v(\theta)q_0 - t_0 - B^i(\theta)] dF(\theta), \]
which must at most be zero. Summing over the $i$'s and using the fact that the buyers’ aggregate payoff is $\sum_i B^i(\theta) = [v(\theta) - \theta]Q(\theta) - U(\theta)$ for any type $\theta$ then yields (13). ■

Define $\|Q\|_\infty = \inf \{q > 0 : \int 1_{\{Q(\theta) \leq q\}} dF(\theta) = 1\}$ to be the essential supremum of the set of quantities traded in equilibrium. Define $\hat{\theta} = \sup \{\theta \in [\underline{\theta}, \bar{\theta}] : Q(\theta) = \|Q\|_\infty\}$, letting $\hat{\theta} = \underline{\theta}$ if this set is empty. If $\|Q\|_\infty = 0$ then the equilibrium essentially features no trade, which implies that even a monopsony could not extract any rent from the seller, that is $w^m = 0$. One now proves that any equilibrium must indeed be such that $\|Q\|_\infty = 0$, and therefore that no equilibrium exists whenever $w^m > 0$. The following result holds.

\textbf{Lemma 7} If $\|Q\|_\infty > 0$, the buyers’ aggregate payoff is zero when a quantity at most equal to $\|Q\|_\infty$ is sold by some type in $[\underline{\theta}, \bar{\theta}]$. Moreover, if $\underline{\theta} < \theta < \bar{\theta}$,
\[ U(\theta) = [v(\theta) - \theta]Q(\theta), \tag{15} \]
so that the buyers’ aggregate payoff is zero when the seller’s type is $\theta$.

\textbf{Proof.} The proof goes through a series of steps.
Step 1 Let \( \theta_0 \in [\underline{\theta}, \overline{\theta}] \) be a type who sells a quantity \( Q(\theta_0) \leq \|Q\|_\infty \), and suppose that \( \theta_0 \) is the only type in \([\underline{\theta}, \overline{\theta}]\) who sells \( Q(\theta_0) \) and that \( Q \) is continuous at \( \theta_0 \). One can then choose \( \theta_a \) and \( \theta_b \) such that \( \underline{\theta} \leq \theta_a \leq \theta_0 < \theta_b \) and apply Lemma 6. As \( t_0 = U(\theta_a) + \theta_a q_0 \),

\[
n \int_{\theta_a}^{\theta_b} [v(\theta)q_0 - U(\theta_a) - \theta_a q_0] dF(\theta) \leq \int_{\theta_a}^{\theta_b} [(v(\theta) - \theta)Q(\theta) - U(\theta)] dF(\theta). \tag{16}
\]

Because \( Q \) is continuous at \( \theta_0 \) and \( U(\theta) = \int_0^\theta Q(\vartheta) d\vartheta + U(\overline{\theta}) \), \( U \) is differentiable at \( \theta_0 \) and \( U''(\theta_0) = -Q(\theta_0) \). It thus follows from the definition (12) of \( q_0 \) that \( q_0 \) goes to \( Q(\theta_0) \) as \( \theta_a \) and \( \theta_b \) go to \( \theta_0 \). Using the fact that \( v, U \) and \( Q \) are continuous at \( \theta_0 \), one can then divide (16) by \( F(\theta_b) - F(\theta_a) \) and take limits as \( \theta_a \) and \( \theta_b \) go to \( \theta_0 \) to obtain

\[
n [v(\theta_0)Q(\theta_0) - U(\theta_0) - \theta_0 Q(\theta_0)] \leq [v(\theta_0) - \theta_0]Q_0 - U(\theta_0)
\]

so that \( [v(\theta_0) - \theta_0]Q(\theta_0) - U(\theta_0) \leq 0 \) as \( n \geq 2 \). Observe that since \( Q \) is decreasing, it has at most a countable number of discontinuity points. Thus, with the exception of such points, this inequality holds for any type \( \theta_0 \) who is the only type in \( [\underline{\theta}, \overline{\theta}] \) who sells \( Q(\theta_0) \leq \|Q\|_\infty \).

Step 2 Let \( \theta_0 \in [\underline{\theta}, \overline{\theta}] \) be a type who sells a quantity \( Q(\theta_0) \leq \|Q\|_\infty \), and suppose now that there exists a maximal interval of types in \( [\underline{\theta}, \overline{\theta}] \) containing \( \theta_0 \), with lower bound \( \theta_1 \) and upper bound \( \theta_2 > \theta_1 \), and such that any type in this interval sells \( Q(\theta_0) \). Observe that one may have \( Q(\theta_0) = \|Q\|_\infty \) and thus \( \theta_1 = \underline{\theta} \), and that one may also have \( \theta_2 = \overline{\theta} \). In any case, since \( \|Q\|_\infty > 0 \) and \( Q(\theta) \) goes to 0 as \( \theta \) goes to infinity, one can choose \( \theta_a \) and \( \theta_b \) such that \( \underline{\theta} \leq \theta_a \leq \theta_1 < \theta_2 < \theta_b \) and apply Lemma 6. Observe that if \( \theta_2 = \overline{\theta} \) and thus \( \theta_b > \overline{\theta} \), the integrals on each side of (13) can be taken over the range \( [\theta_a, \overline{\theta}] \). Taking limits as \( \theta_a \) goes to \( \theta_1 \) and \( \theta_b \) goes to \( \theta_2 \) yields

\[
n \int_{\theta_1}^{\theta_2} [v(\theta)Q(\theta_0) - U(\theta) - \theta_0 Q(\theta_0)] dF(\theta) \leq \int_{\theta_1}^{\theta_2} [(v(\theta) - \theta)Q(\theta_0) - U(\theta)] dF(\theta)
\]

so that \( \int_{\theta_1}^{\theta_2} [(v(\theta) - \theta)Q(\theta_0) - U(\theta)] dF(\theta) \leq 0 \) as \( n \geq 2 \).

Step 3 It follows from Steps 1 and 2 that, with the possible exception of quantities traded by at most a countable number of types in \([\underline{\theta}, \overline{\theta}]\), the buyers’ aggregate payoff is at most zero when any quantity in \( Q([\underline{\theta}, \overline{\theta}]) \cap [0, \|Q\|_\infty] \) is sold. Because the buyer’s aggregate payoff must be at least zero since each buyer always has the option not to trade, it follows that the buyer’s aggregate payoff is exactly zero when any quantity in \( Q([\underline{\theta}, \overline{\theta}]) \cap [0, \|Q\|_\infty] \) is sold, with the possible exception of quantities traded by a set of types of measure zero under the distribution \( F \). Clearly each buyer’s payoff is exactly equal to zero.
Step 4 Now, let \( \theta_0 \in (\underline{\theta}, \overline{\theta}) \) be a type who sells a quantity \( Q(\theta_0) \in (0, \|Q\|_{\infty}) \), and suppose that there exists a maximal interval of types in \( (\underline{\theta}, \overline{\theta}) \) containing \( \theta_0 \), with lower bound \( \theta_1 \) and upper bound \( \theta_2 > \theta_1 \), and such that any type in this interval sells \( Q(\theta_0) \). The difference with Step 2 is that one must have \( \theta_1 > \theta \) as \( Q(\theta_0) < \|Q\|_{\infty} \). One can therefore choose \( \theta_a < \theta_1 < \theta_b < \theta_2 \), and apply Lemma 6. Taking the limit as \( \theta_a \) goes to \( \theta_1 \) then yields

\[
\int_{\theta_a}^{\theta_2} \left[ (v(\theta) - \theta)Q(\theta_0) - U(\theta) \right] dF(\theta) \leq 0
\]

(17) for all \( \theta \in (\theta_1, \theta_2) \). Similarly, since \( Q(\theta_0) > 0 \) and \( Q(\theta) \) goes to 0 as \( \theta \) goes to infinity, one can choose \( \theta_a \) and \( \theta_b \) such that \( \theta_1 < \theta_a < \theta_2 < \theta_b \) and apply Lemma 6. As in Step 2, observe that if \( \theta_2 = \overline{\theta} \) and thus \( \theta_1 > \overline{\theta} \), the integrals on each side of (13) can be taken over the range \([\theta_a, \overline{\theta}]\). Taking limits as \( \theta_2 \) goes to \( \theta_1 \) then yields

\[
\int_{\theta_1}^{\theta_2} \left[ (v(\theta) - \theta)Q(\theta_0) - U(\theta) \right] dF(\theta) \leq 0
\]

(18) for all \( \theta \in (\theta_1, \theta_2) \). Since \( \int_{\theta_1}^{\theta_2} \left[ (v(\theta) - \theta)Q(\theta_0) - U(\theta) \right] dF(\theta) = 0 \) by Step 3, it follows from (17) and (18) that the mapping \( \theta \mapsto \int_{b}^{\theta} \left[ (v(\theta) - \theta)Q(\theta_0) - U(\theta) \right] dF(\theta) \) is identically zero over \((\theta_1, \theta_2)\). Since \( v \) is continuous and \( Q(\theta) = Q(\theta_0) \) for all \( \theta \in (\theta_1, \theta_2) \), it follows by differentiation that (15) holds for all \( \theta \in (\theta_1, \theta_2) \).

Step 5 If there exists a maximal interval of types in \([\theta, \overline{\theta}]\) with lower bound \( \theta_1 \) and upper bound \( \overline{\theta} > \theta_1 \), and such that any type in this interval sells zero, then clearly all these types must obtain a zero payoff, for otherwise the buyers’ aggregate payoff when a quantity zero is sold would be strictly negative, contradicting Step 3. It follows that (15) holds for all \( \theta \in (\theta_1, \overline{\theta}) \).

Step 6 By Steps 4 and 5, (15) holds for any type in the interior of a pooling interval contained in \([\underline{\theta}, \overline{\theta}]\), as long as the quantity sold by all types in this interval is strictly below \( \|Q\|_{\infty} \). By Steps 1 and 3, (15) also holds for any type who is the only type in \([\theta_1, \overline{\theta}]\) who sells a quantity at most \( \|Q\|_{\infty} \), except perhaps for a set of set of types of measure zero under the distribution \( F \). Thus (15) holds for any type in \((\underline{\theta}, \overline{\theta})\), except perhaps for a set of set of types of measure zero under the distribution \( F \). Now let \( \theta_0 \in (\underline{\theta}, \overline{\theta}) \) be one of these possibly problematic types. If \( v(\theta_0) \neq \theta_0 \), one can deduce from the fact that \( v \) and \( U \) are continuous and that (15) holds along sequences of types converging to \( \theta_0 \) from below and from above that \( Q \) is continuous at \( \theta_0 \) and that (15) also holds at \( \theta_0 \). If \( v(\theta_0) = \theta_0 \), one can deduce from the continuity of the functions \( v \) and \( U \) and from the fact that (15) holds along a sequence of types converging to \( \theta_0 \) that \( U(\theta_0) = 0 \), so that (15) also holds at \( \theta_0 \) since \( v(\theta_0) = \theta_0 \), no matter the value of \( Q(\theta_0) \).
**Step 7** By Step 6, (15) holds for any type in $(\hat{\theta}, \overline{\theta})$. To conclude, one need only to check that the buyers’ aggregate payoff is zero when a quantity $\|Q\|_\infty$ is sold. One knows from Steps 2 and 3 that the buyers’ aggregate payoff is zero when the quantity $\|Q\|_\infty$ is sold by a non trivial interval of types in $[\underline{\theta}, \overline{\theta}]$. Now, if $\|Q\|_\infty$ is sold by $\theta$ only, so that $\hat{\theta} = \underline{\theta}$, then $Q$ must be continuous at $\underline{\theta}$, by definition of $\|Q\|_\infty$. Since, by Step 6, (15) holds along a sequence of types converging to $\underline{\theta}$ and since $v$, $U$ and $Q$ are continuous at $\underline{\theta}$, (15) also holds at $\underline{\theta}$ in this case. The result follows.

To complete the proof of Proposition 7, we show that $\|Q\|_\infty = 0$. Supposing by way of contradiction that $\|Q\|_\infty > 0$, three cases need to be distinguished.

**Case 1** Suppose first that $\hat{\theta} = \underline{\theta}$, so that $Q(\theta) < \|Q\|_\infty \leq 1$ for all $\theta > \underline{\theta}$. By Lemma 7, it follows that (15) holds everywhere over $(\underline{\theta}, \overline{\theta})$. Moreover, since $U'(\theta) = -Q(\theta)$ except at most for a countable number of types, the mapping $\theta \mapsto U(\theta) + \theta$ is strictly increasing. Any buyer $i$ can deviate by adding to his equilibrium menu the contract $(1, U(\theta_0) + \theta_0)$, for some $\theta_0 > \underline{\theta}$. All types $\theta < \theta_0$ are strictly better off trading this contract, while all types $\theta > \theta_0$ are strictly worse off trading it. As the equilibrium under scrutiny is assumed to be conservative, the latter do not change their behavior following buyer $i$’s deviation. The change in buyer $i$’s payoff induced by this deviation is thus

$$\int_\underline{\theta}^{\theta_0} [v(\theta) - U(\theta_0) - \theta_0 - B^i(\theta)] dF(\theta),$$

which must at most be zero. Summing over the $i$’s and using the fact that the buyers’ aggregate payoff is $\sum_i B^i(\theta) = [v(\theta) - \theta]Q(\theta) - U(\theta) = 0$ for any type $\theta \in (\underline{\theta}, \overline{\theta})$ then yields

$$g(\theta_0) = \int_\underline{\theta}^{\theta_0} [v(\theta) - U(\theta_0) - \theta_0] dF(\theta) \leq 0$$

for all $\theta_0 > \underline{\theta}$. Observe that $g$ is absolutely continuous and differentiable except at most for a countable number of types, with a derivative that satisfies

$$g'(\theta_0) = [v(\theta_0) - U(\theta_0) - \theta_0]f(\theta_0) - [1 - Q(\theta_0)]F(\theta_0) = [1 - Q(\theta_0)]\{[v(\theta_0) - \theta_0]f(\theta_0) - F(\theta_0)\},$$

where the second equality follows from the fact that (15) holds everywhere over $(\underline{\theta}, \overline{\theta})$. One now proves that $g'$ whenever defined is strictly positive in a right-neighborhood of $\underline{\theta}$, which implies that $g(\theta_0) > 0$ for $\theta_0$ close enough to $\underline{\theta}$, a contradiction. To prove this, observe first that $1 - Q(\theta_0) > 1 - \|Q\|_\infty \geq 0$ as $\theta_0 > \underline{\theta}$. Second, since $Q(\theta)$ goes to $\|Q\|_\infty > 0$ as $\theta$ goes to $\underline{\theta}$, and since $U'(\theta) = -Q(\theta)$ except at most for a countable number of types, one has $U(\underline{\theta}) > 0$. As $v$ and $U$ are continuous, this in turn implies by (15) that $v(\underline{\theta}) > \underline{\theta}$. Since by
assumption \( f \) is bounded away from zero over \([\theta, \tilde{\theta}]\) and \( F \) vanishes at \( \tilde{\theta} \), this implies that 
\[ (v(\theta_0) - \theta_0) f(\theta_0) - F(\theta_0) > 0 \]
in a right-neighborhood of \( \tilde{\theta} \). The claim then follows from the above expression for \( g'(\theta_0) \).

**Case 2** Suppose next that \( \hat{\theta} = \tilde{\theta} \), so that all types in \((\hat{\theta}, \tilde{\theta})\) exactly sell \( \|Q\|_\infty \). Since by Lemma 7 the buyers’ aggregate payoff is zero when the quantity \( \|Q\|_\infty \) is sold, this must be against a transfer \( E[v(\theta)]\|Q\|_\infty \). Any buyer \( i \) can deviate by adding to his equilibrium menu the contract \((q_0, U(\theta_0) + \theta_0q_0)\), for some \( q_0 < \|Q\|_\infty \) and \( \theta_0 \in (\hat{\theta}, \tilde{\theta}) \). All types \( \theta > \theta_0 \) are strictly better off trading this contract, while all types \( \theta < \theta_0 \) are strictly worse off trading it. As the equilibrium under scrutiny is assumed to be conservative, the latter do not change their behavior following buyer \( i \)’s deviation. Observe that \( U(\theta_0) = \{E[v(\theta)] - \theta_0\}\|Q\|_\infty \). The change in buyer \( i \)'s payoff induced by this deviation is thus
\[
\int_{\theta_0}^{\tilde{\theta}} [v(\theta)q_0 - \{E[v(\theta)] - \theta_0\}\|Q\|_\infty - \theta_0q_0 - B_i(\theta)] dF(\theta)
\]
which must at most be zero. Summing over the \( i \)'s and using the fact that the buyers’ aggregate payoff is \( \sum_i B_i(\theta) = [v(\theta) - \theta]Q(\theta) - U(\theta) = \{v(\theta) - E[v(\theta)]\}\|Q\|_\infty \) for any type \( \theta \in (\hat{\theta}, \tilde{\theta}) \) then yields, when one lets \( q_0 \) go to \( \|Q\|_\infty \),
\[
(n - 1)\|Q\|_\infty \int_{\theta_0}^{\tilde{\theta}} \{v(\theta) - E[v(\theta)]\} dF(\theta) \leq 0,
\]
so that \( \int_{\theta_0}^{\tilde{\theta}} \{v(\theta) - E[v(\theta)]\} dF(\theta) \leq 0 \) as \( n \geq 2 \) and \( \|Q\|_\infty > 0 \). This, however, is impossible as \( \theta_0 > \hat{\theta} \) and \( v \) is strictly increasing.

**Case 3** Suppose finally that \( \underline{\theta} < \hat{\theta} < \tilde{\theta} \), so that all types in \((\underline{\theta}, \hat{\theta})\) exactly sell \( \|Q\|_\infty \). Since by Lemma 7 the buyers’ aggregate payoff is zero when the quantity \( \|Q\|_\infty \) is sold, this must be against a transfer \( E[v(\theta) \mid \theta \leq \hat{\theta}]\|Q\|_\infty \). One can then choose \( \theta_a \) and \( \theta_b \) such that \( \underline{\theta} < \theta_a < \hat{\theta} < \theta_b \) and apply Lemma 6 to get (16). As \( \theta_b \) goes to \( \hat{\theta} \), \( q_0 \) goes to \( \|Q\|_\infty \). Since \( U(\theta) = \{E[v(\theta) \mid \theta \leq \hat{\theta}]\\|Q\|_\infty \) for all \( \theta \in (\hat{\theta}, \tilde{\theta}) \), one then obtains
\[
\frac{n}{\theta_a} \int_{\theta_a}^{\hat{\theta}} \{v(\theta) - E[v(\theta) \mid \theta \leq \hat{\theta}]\}\|Q\|_\infty dF(\theta) \leq \int_{\theta_a}^{\hat{\theta}} \{v(\theta) - E[v(\theta) \mid \theta \leq \hat{\theta}]\}\|Q\|_\infty dF(\theta)
\]
so that \( \int_{\theta_a}^{\hat{\theta}} \{v(\theta) - E[v(\theta) \mid \theta \leq \hat{\theta}]\} dF(\theta) \leq 0 \) as \( n \geq 2 \) and \( \|Q\|_\infty > 0 \). Using the fact that \( v \) is continuous, one can then divide this inequality by \( F(\hat{\theta}) - F(\theta_a) \) and take the limit as \( \theta_a \) goes to \( \hat{\theta} \) to obtain \( v(\hat{\theta}) \leq E[v(\theta) \mid \theta \leq \hat{\theta}] \). This, however, is impossible as \( v \) is strictly increasing. Hence the result.

**Proof of Proposition 8.** The proof goes through a series of steps.
Step 1 Given the menus offered, any best response of the seller leads to aggregate trades
\((1, p^*)\) for types \(\theta < p^*\) and \((0, 0)\) for types \(\theta > p^*\). Assuming that each buyer trades the same quantity with each type of the seller, all buyers obtain a zero payoff as \(p^* = E[v(\theta) | \theta \leq p^*]\).

Step 2 An additional contract \((q, t)\) attracts a type \(\theta \leq p^*\) only if \(t \geq p^*q\), since she has the option to trade any quantity at unit price \(p^*\). Hence each type \(\theta \leq p^*\) faces the same problem, namely to optimally use the deviating buyer’s and the other buyers’ offers to sell her whole endowment at the maximum price. One can therefore construct the seller’s strategy in such a way that each type \(\theta \leq p^*\) selects the same contract \((q, t)\) from the deviating buyer’s menu. Since \(t \geq p^*q\) and \(p^* = E[v(\theta) | \theta \leq p^*]\), this implies that no deviation can be profitable over types \(\theta \leq p^*\). Observe that since each type \(\theta \leq p^*\) attempts to maximize
\[t - \theta q + (p^* - \theta)(1 - q) = t - p^*q + p^* - \theta\]
over the menu of contracts \((q, t)\) offered by the deviating buyer, one has \(t - p^*q \geq t - p^*q\) for any such contract.

Step 3 If \(\theta > p^*\), a deviating buyer may also attempt to attract some types \(\theta > p^*\). Over this set of types, he effectively acts as a monopsony, since none of them has an incentive to sell to the other buyers at unit price \(p^*\). Now, take any contract \((q, t)\) in the deviating buyer’s menu, and suppose that \(q > q\). Then, since \(t - p^*q \geq t - p^*q\) by Step 2, one a fortiori has \(t - \theta q > t - \theta q\) for all \(\theta > p^*\), so that each type \(\theta > p^*\) would rather trade \((q, t)\) than \((q, t)\). It follows that the types \(\theta > p^*\) sell at most \(q\) to the deviating buyer. For any fixed contract \((q, t)\) such that \(t > p^*q\), the problem of the deviating buyer is to maximize
\[\int_{\theta}^{\theta} [v(\theta)q(\theta) - t(\theta)] dF(\theta),\]
subject to the seller’s incentive compatibility and individual rationality constraints
\[t - p^*q \geq t(\theta) - p^*q(\theta),\]
\[t(\theta) - \theta q(\theta) \geq t(\theta') - \theta q(\theta'),\]
\[t(\theta) - \theta q(\theta) \geq 0,\]
for all \((\theta, \theta') \in (p^*, \theta] \times [\theta, \theta]\), and to the two additional constraints that
\[(q(\theta'), t(\theta')) = (q, t)\]
for all \(\theta' \in [\theta, p^*]\) and that
\[q(\theta) \leq q\]
for all \( \theta \in (p^*, \bar{\theta}] \). This last constraint along with the constraint that \( t - p^* q \geq t(\theta) - p^* q(\theta) \) implies that \( t - \theta' q \geq t(\theta) - \theta' q(\theta) \) for all \( (\theta, \theta') \in (p^*, \bar{\theta}] \times [\bar{\theta}, p^*] \). Thus the deviating buyer’s payoff is at most equal to the value of the problem studied in the proof of Lemma 5, with \( (\theta_0, \theta_1, Q_0, Q_1) = (p^*, \bar{\theta}, q, 0) \), that is, by (11), \( q \sup_{\theta \in [p^*, \bar{\theta}]} \{w(\theta)\} = 0 \). The result follows. ■

**Proof of Proposition 9.** Consider a conservative equilibrium in which each type \( \theta \) sells an aggregate quantity \( Q(\theta) \) and obtains a payoff \( U(\theta) \). Define \( B^i(\theta) \) as the payoff obtained by buyer \( i \) from trading with type \( \theta \). Define also \( \theta_0 \) as the supremum of those types that sell their whole endowment, setting \( \theta_0 = \bar{\theta} \) if there are none. By the maximum theorem, one can without loss of generality assume that type \( \theta_0 \) sells her whole endowment. If \( \theta_0 = \bar{\theta} \), the result follows, as \( Q \) is decreasing by incentive compatibility. Otherwise, take some \( \theta_1 \in (\theta_0, \bar{\theta}] \), and let \( (q^i(\theta_1), t^i(\theta_1)) \) be the contract traded by type \( \theta_1 \) with buyer \( i \), so that

\[
Q(\theta_1) = \sum_i q^i(\theta_1) \quad \text{and} \quad U(\theta_1) = \sum_i t^i(\theta_1) - \theta_1 \sum_i q^i(\theta_1). \tag{19}
\]

Any buyer \( i \) can deviate by adding to his equilibrium menu the contract

\[
c^i = (q^i(\theta_1) + 1 - Q(\theta_1), t^i(\theta_1) + \theta_1[1 - Q(\theta_1)]).
\]

The seller reacts to this deviation depending on her type \( \theta \). Each type \( \theta > \theta_1 \) strictly prefers \( (q^i(\theta_1), t^i(\theta_1)) \) to \( c^i \), because the unit price \( \theta_1 \) at which \( c^i \) allows her to sell the quantity increment \( 1 - Q(\theta_1) \) is too low from her point of view. As the equilibrium under scrutiny is assumed to be conservative, type \( \theta \) does not change her behavior following buyer \( i \)'s deviation. Each type \( \theta < \theta_1 \) can sell her whole endowment by trading \( c^i \) together with the contracts \( (q^j(\theta_1), t^j(\theta_1)), j \neq i \), thereby obtaining a payoff

\[
t^i(\theta_1) + \theta_1[1 - Q(\theta_1)] + \sum_{j \neq i} t^j(\theta_1) - \theta = U(\theta_1) + \theta_1 - \theta > U(\theta),
\]

where the strict inequality follows from the fact that \( U(\theta) = \int_{\theta_1}^{\theta} Q(\theta) \, d\theta + U(\theta_1) \) by the envelope theorem, and that \( Q < 1 \) over \( (\theta_0, \theta_1] \). Since \( U(\theta) \) is the highest payoff type \( \theta \) can obtain by rejecting \( c^i \), it follows that she trades \( c^i \) following buyer \( i \)'s deviation. The change in buyer \( i \)'s payoff induced by this deviation is thus

\[
\int_{\bar{\theta}}^{\theta_1} \{[q^i(\theta_1) + 1 - Q(\theta_1)]v(\theta) - t^i(\theta_1) - \theta_1[1 - Q(\theta_1)] - B^i(\theta)\} \, dF(\theta),
\]

which must at most be zero. Using the definition of \( w \), we obtain

\[
[q^i(\theta_1) + 1 - Q(\theta_1)]w(\theta_1) \leq \int_{\bar{\theta}}^{\theta_1} [t^i(\theta_1) - \theta_1 q^i(\theta_1) + B^i(\theta)] \, dF(\theta).
\]
Summing over the $i$'s and using (19) and the fact that the buyers’ aggregate payoff is
$\sum_i B^i(\theta) = [v(\theta) - \theta]Q(\theta) - U(\theta)$ for any type $\theta$ then yields

$$Q(\theta_1) + n[1 - Q(\theta_1)]w(\theta_1) \leq \int_{\theta}^{\theta_1} \{[v(\theta) - \theta]Q(\theta) - [U(\theta) - U(\theta_1)]\} dF(\theta)$$

$$= \int_{\theta}^{\theta_1} [v(\theta) - \theta]Q(\theta) dF(\theta) - \int_{\theta}^{\theta_1} F(\theta)Q(\theta) d\theta,$$

where the equality follows from an integration by parts. Note that the right-hand side of (20) is (9). By incentive compatibility, $Q$ is decreasing, which in particular implies that $Q(\theta) \geq Q(\theta_1)$ for all $\theta \in [\theta, \theta_1]$; moreover, $Q(\theta) = Q_0$ for all $\theta \in [\theta, \theta_0]$. It follows that the buyers’ aggregate payoff on the right-hand side of (20) is at most equal to the value of the problem studied in the proof of Lemma 5, with $(\theta_0, \theta_1, Q_0, Q_1) = (\theta_0, \theta_1, 1, Q(\theta_1))$, that is, by (11), $Q(\theta_1)w(\theta_1) + [1 - Q(\theta_1)]\sup_{\theta \in [\theta_0, \theta_1]} \{w(\theta)\}$. Substituting in (20) and simplifying as $Q(\theta_1) < 1$, one finally obtains that

$$nw(\theta_1) \leq \sup_{\theta \in [\theta_0, \theta_1]} \{w(\theta)\}.$$

Since this inequality holds for all $\theta_1 \in (\theta_0, \bar{\theta}]$, one can take suprema to get

$$n \sup_{\theta_1 \in (\theta_0, \bar{\theta}]} \{w(\theta_1)\} \leq \sup_{\theta_1 \in (\theta_0, \bar{\theta}]} \left\{\sup_{\theta \in [\theta_0, \theta_1]} \{w(\theta)\}\right\} \leq \sup_{\theta \in [\theta_0, \bar{\theta}]} \{w(\theta)\},$$

which, by continuity of $w$, and because $n \geq 2$, implies that

$$\sup_{\theta \in [\theta_0, \bar{\theta}]} \{w(\theta)\} \leq 0.$$

Using the definition of $p^*$ along with the fact that $w$ is strictly decreasing beyond $\bar{\theta}$, this implies that $\theta_0 \geq p^*$, so that $Q(\theta) = 1$ for $\theta < p^*$. It follows that the buyers’ aggregate payoff is at most equal to the value of the problem studied in the proof of Lemma 5, with $(\theta_0, \theta_1, Q_0, Q_1) = (p^*, \bar{\theta}, 1, 0)$, that is, by (11), $\sup_{\theta \in [p^*, \bar{\theta}]} \{w(\theta)\} = 0$. Proceeding as for (10), it is easy to check that the buyers’ aggregate payoff is

$$\int_{\theta}^{\bar{\theta}} w(\theta) d(1 - Q^+)(\theta) = \int_{p^*}^{\bar{\theta}} w(\theta) d(1 - Q^+)(\theta),$$

where the equality reflects the fact that the measure $d(1 - Q^+)$ does not charge $[\theta, p^*)$ since $Q = 1$ over $[\theta, p^*]$. Since by assumption $w < 0$ over $(p^*, \bar{\theta}]$, and since the buyers’ aggregate payoff must be at least zero in equilibrium, it follows from (21) that $d(1 - Q^+)$ is a unit mass at $p^*$, so that $Q = 0$ over $(p^*, \bar{\theta}]$. Hence the result. \[\blacksquare\]
Proof of Proposition 10. Suppose a conservative equilibrium exists in which some buyer $i$ offers a contract $c^i = (q^i, t^i)$ at unit price $\frac{t^i}{q^i} > p^*$. One must have $q^i < 1$ otherwise $c^i$ would give types $\theta < \frac{t^i}{q^i}$ more than their equilibrium payoff. Any other buyer $j$ could offer a menu consisting of the no-trade contract and of the contract

$$c^j(\varepsilon) = (1 - q^i, (p^* - \varepsilon)(1 - q^i)),$$

where $0 < \varepsilon < \frac{t^i - p^* q^i}{1 - q^i}$. If both $c^i$ and $c^j(\varepsilon)$ were available, each type $\theta < p^* - \varepsilon$ would sell her whole endowment at price $t^i + (p^* - \varepsilon)(1 - q^i)$ by trading $c^i$ with buyer $i$ and $c^j(\varepsilon)$ with buyer $j$, thereby increasing her payoff by $t^i - p^* q^i - \varepsilon(1 - q^i)$ compared to what she obtains in equilibrium. By contrast, types $\theta > p^* - \varepsilon$ do not gain by trading $c^j(\varepsilon)$ with buyer $j$, since the unit price at which this contract is issued is too low from their point of view. Buyer $j$'s equilibrium payoff is thus at least

$$\int_{\theta}^{p^* - \varepsilon} [v(\theta) - p^* + \varepsilon](1 - q^i) dF(\theta) = (1 - q^i)w(p^* - \varepsilon),$$

which by definition of $p^*$ is strictly positive for some well chosen $\varepsilon \in \left(0, \frac{t^i - p^* q^i}{1 - q^i}\right)$. This, however, is impossible, since each buyer’s payoff is zero in any conservative equilibrium by Proposition 8. Hence no contract can be issued at a price strictly above $p^*$ in such an equilibrium. The result follows. Observe that if $p^* \leq \overline{\theta}$, so that $p^*$ is in the support of the seller’s type distribution, a much simpler proof goes as follows: if $\frac{t^i}{q^i} > p^*$, then $\frac{t^i - \theta q^i}{1 - q^i} < p^*$. But then $t^i - \theta q^i > p^* - \theta$ for all types $\theta \in \left[\max\left\{\theta, \frac{t^i - \theta q^i}{1 - q^i}\right\}, p^*\right)$, so that $c^i$ would give any such type more than her equilibrium payoff, a contradiction. This argument breaks down whenever $p^* > \overline{\theta}$, so that $p^*$ does not correspond to a possible type for the seller. ■

Proof of Corollary 3. From Proposition 10, no contract is issued, and a fortiori traded, at a unit price strictly above $p^*$ in a conservative equilibrium. Suppose first that a contract with unit price strictly below $p^*$ is traded by some type $\theta < p^*$ in a conservative equilibrium. Then, since the aggregate allocation traded by type $\theta$ is $(1, p^*)$, a contract with unit price strictly above $p^*$ must be traded in this equilibrium, a contradiction. Suppose next that $p^* \leq \overline{\theta}$ and that a contract with unit price strictly below $p^*$ is traded by type $p^*$ in a conservative equilibrium. Then, since type $p^*$’s payoff is zero, a contract with unit price strictly above $p^*$ must be traded in this equilibrium, a contradiction. Hence the result. ■

Proof of Proposition 11. Fix some conservative equilibrium and some buyer $i$, and define the set $\mathfrak{A}^{-i}$ as in the proof of Proposition 4. One must show that $(1, p^*) \in \mathfrak{A}^{-i}$.  

55
Assume first that $E[v(\theta)] > \overline{\theta}$, so that $p^* = E[v(\theta)]$. Then the argument is exactly the same as in the first case examined in the proof of Proposition 4.

Assume next that $E[v(\theta)] \leq \overline{\theta}$, so that $p^* \leq \overline{\theta}$. Suppose the aggregate allocation $(1, p^*)$ traded by types $\theta < p^*$ does not belong to $A^{-i}$. Since $A^{-i}$ is compact, there exists an open set of $[0, 1] \times \mathbb{R}_+$ that contains $(1, p^*)$ and that does not intersect $A^{-i}$. Moreover, any allocation $(Q^{-i}, T^{-i}) \in A^{-i}$ is such that $T^{-i} \leq p^*Q^{-i}$ by Proposition 10. For $\varepsilon$ close enough to zero, any solution $(Q^{-i}(p^* - \varepsilon, 1), T^{-i}(p^* - \varepsilon, 1))$ to the maximization problem that defines $\varepsilon^{-i}(p^* - \varepsilon, 1)$ must be such that $Q^{-i}(p^* - \varepsilon, 1)$ is bounded away from one: otherwise, there would exist a sequence $\{\varepsilon_n\}_{n \geq 1}$ converging to zero and a sequence $\{(Q^{-i}(p^* - \varepsilon_n, 1), T^{-i}(p^* - \varepsilon_n, 1))\}_{n \geq 1}$ in $A^{-i}$ such that the sequence $\{Q^{-i}(p^* - \varepsilon_n, 1)\}_{n \geq 1}$ converges to one and

$$T^{-i}(p^* - \varepsilon_n, 1) - (p^* - \varepsilon_n)Q^{-i}(p^* - \varepsilon_n, 1) \geq 0$$

for all $n \geq 1$. Taking limits as $n$ goes to infinity and using the fact $A^{-i}$ is compact, this would imply that the quantity one can be traded in an aggregate allocation in $A^{-i}$ at a price at least $p^*$, a contradiction. Now let $(\overline{Q}^{-i}(p^* - \varepsilon, 1), \overline{T}^{-i}(p^* - \varepsilon, 1))$ be the solution to the maximization problem that defines $\varepsilon^{-i}(p^* - \varepsilon, 1)$ with highest quantity traded. From the above argument, one can choose $\varepsilon$ in such a way that $\overline{Q}^{-i}(p^* - \varepsilon, 1) < 1$. By definition of $p^*$, one can further choose $\varepsilon$ in such a way that $w(p^* - \varepsilon) > 0$. Buyer $i$ could offer a menu consisting of the no-trade contract and of the contract

$$c^i(\varepsilon) = (1 - \overline{Q}^{-i}(p^* - \varepsilon, 1), (p^* - \varepsilon)[1 - \overline{Q}^{-i}(p^* - \varepsilon, 1)]).$$

Consider any type $\theta < p^* - \varepsilon$, and let $(Q^{-i}(\theta, 1), T^{-i}(\theta, 1))$ be a solution to the maximization problem that defines $\varepsilon^{-i}(\theta, 1)$. By incentive compatibility, $Q^{-i}(\theta, 1) \geq \overline{Q}^{-i}(p^* - \varepsilon, 1)$. If $Q^{-i}(\theta, 1) = \overline{Q}^{-i}(p^* - \varepsilon, 1)$ and thus $T^{-i}(\theta, 1) = \overline{T}^{-i}(p^* - \varepsilon, 1)$, type $\theta$ could sell her whole endowment at price $T^{-i}(\theta, 1) + (p^* - \varepsilon)[1 - \overline{Q}^{-i}(p^* - \varepsilon, 1)]$ by trading the aggregate allocation $(Q^{-i}(\theta, 1), T^{-i}(\theta, 1))$ with buyer $j \neq i$ and the contract $c^i(\varepsilon)$ with buyer $i$, thereby increasing her payoff by $(p^* - \varepsilon - \theta)[1 - \overline{Q}^{-i}(p^* - \varepsilon, 1)]$ compared to what she could obtain from trading with buyers $j \neq i$ only. If $Q^{-i}(\theta, 1) > \overline{Q}^{-i}(p^* - \varepsilon, 1)$, one has

$$T^{-i}(p^* - \varepsilon, 1) - (p^* - \varepsilon)\overline{Q}^{-i}(p^* - \varepsilon, 1) > T^{-i}(\theta, 1) - (p^* - \varepsilon)\overline{Q}^{-i}(\theta, 1)$$

by definition of $\overline{Q}^{-i}(p^* - \varepsilon, 1)$, from which it follows that

$$\overline{T}^{-i}(p^* - \varepsilon, 1) + (p^* - \varepsilon)[1 - \overline{Q}^{-i}(p^* - \varepsilon, 1)] > T^{-i}(\theta, 1) + (p^* - \varepsilon)[1 - Q^{-i}(\theta, 1)]$$

$$\geq T^{-i}(\theta, 1) + \theta[1 - Q^{-i}(\theta, 1)]$$

56
and finally that

\[ T^{-i}(p^* - \varepsilon, 1) + (p^* - \varepsilon)[1 - Q^{-i}(p^* - \varepsilon, 1)] - \theta > T^{-i}(\theta, 1) - \theta Q^{-i}(\theta, 1). \]

Thus, by trading the aggregate allocation \((Q^{-i}(p^* - \varepsilon, 1), T^{-i}(p^* - \varepsilon, 1))\) with buyer \(j \neq i\) and the contract \(c^i(\varepsilon)\) with buyer \(i\), type \(\theta\) would strictly increase her payoff compared to what she could obtain from trading with buyers \(j \neq i\) only. Thus, in any case, all types \(\theta < p^* - \varepsilon\) would trade \(c^i(\varepsilon)\) if this contract were offered by buyer \(i\). By contrast, types \(\theta > p^* - \varepsilon\) do not gain by trading \(c^i(\varepsilon)\) with buyer \(i\), since the unit price at which this contract is issued is too low from their point of view. Buyer \(i\)'s equilibrium payoff is thus at least

\[ \int_{\bar{\theta}}^{p^* - \varepsilon} [v(\theta) - p^* + \varepsilon][1 - \overline{Q}^{-i}(p^* - \varepsilon, 1)] dF(\theta) = [1 - \overline{Q}^{-i}(p^* - \varepsilon, 1)] w(p^* - \varepsilon), \]

which is strictly positive by assumption. This, however, is impossible, since each buyer’s payoff is zero in any conservative equilibrium by Proposition 8. The result follows. ■

**Proof of Proposition 12.** Fix some conservative equilibrium and some buyer \(i\), and define the function \(z^{-i}\) as in the proof of Proposition 5. In line with (3), one can show that

\[ z^{-i}(\theta, Q) \geq z^{-i}(\theta', Q) + (\theta' - \theta)Q \]

for all \((Q, \theta, \theta') \in [0, 1] \times [\bar{\theta}, \bar{\theta}]^2\) such that \(\theta \geq \theta'\), so that the mapping \(\theta \mapsto z^{-i}(\theta, Q) + \theta Q\) is increasing over \([\bar{\theta}, \bar{\theta}]\) for all \(Q \in [0, 1]\). Proceeding as for (7), one can further show that if this function is constant over some interval of types, then, for any type \(\theta\) in this interval, and for any solution \((Q^{-i}(\theta, Q), T^{-i}(\theta, Q))\) to the maximization problem that defines \(z^{-i}(\theta, Q)\), one has \(Q^{-i}(\theta, Q) = Q\), so that there is an aggregate allocation in \(\mathcal{A}^{-i}\) that allows the seller to exactly trade the quantity \(Q\). One now shows that this is the case for any quantity \(Q\) close enough to zero, which implies the result. To see this, fix some \(\theta_0 \in (\bar{\theta}, \min \{p^*, \bar{\theta}\})\) and some \(Q_0 \in (0, 1)\), and suppose that for each \((\theta', \theta'') \in [\bar{\theta}, \bar{\theta}]^2\) such that \(\theta' < \theta_0 < \theta''\), one has

\[ z^{-i}(\theta', Q_0) + \theta'Q_0 < z^{-i}(\theta_0, Q_0) + \theta_0Q_0 < z^{-i}(\theta'', Q_0) + \theta''Q_0. \]

Then buyer \(i\) could offer a menu consisting of the no-trade contract and of a contract \((1 - Q_0, t_0)\) such that \(\theta_0\) is indifferent between trading the contract \((1 - Q_0, t_0)\) with buyer \(i\) along with some aggregate allocation in \(\mathcal{A}^{-i}\) with buyers \(j \neq i\), and trading with buyers \(j \neq i\) only, and therefore getting her equilibrium utility as shown in Proposition 11:

\[ t_0 - \theta_0(1 - Q_0) + z^{-i}(\theta_0, Q_0) = p^* - \theta_0. \]
Now, from (23), all types $\theta > \theta_0$ strictly prefer accepting buyer $i$’s offer to selling their whole endowment at price $p^*$, while all types $\theta < \theta_0$ strictly prefer to their whole endowment at price $p^*$. As for types $\theta > p^*$, they satisfy $z^{-i}(\theta, Q_0) = 0$ since they obtain a zero payoff in equilibrium. Hence any such type accepts buyer $i$’s offer if $t_0 > \theta(1 - Q_0)$, or equivalently $\theta < \theta_1$, where

$$t_0 = \theta_1(1 - Q_0) = \theta_0(1 - Q_0) + p^* - \theta_0 - z^{-i}(\theta_0, Q_0).$$

It is easily checked that $\theta_1 \geq p^*$ if and only if $(p^* - \theta_0)Q_0 \geq z^{-i}(\theta_0, Q_0)$, which is indeed the case since, by Proposition 10, no contract is issued at a price strictly above $p^*$ in a conservative equilibrium. It thus follows that the contract $(1 - Q_0, t_0)$ offered by buyer $i$ attracts all types in some interval $(\theta_0, \theta_1)$, with $\theta_0 < p^* \leq \theta_1$, that types $\theta_0$ and $\theta_1$ are indifferent, and that all other types reject buyer $i$’s offer. Buyer $i$’s equilibrium payoff is thus at least

$$\int_{\theta_0}^{\theta_1} [v(\theta)(1 - Q_0) - t_0] dF(\theta). \quad (24)$$

Now let $Q_0$ go to zero. Then $z^{-i}(\theta_0, Q_0)$ goes to zero as $(p^* - \theta_0)Q_0 \geq z^{-i}(\theta_0, Q_0) \geq 0$, so that $t_0$ and $\theta_1$ go to $p^*$. Hence the limit of (24) is $\int_{\theta_0}^{p^*} [v(\theta) - p^*] dF(\theta)$, which is strictly positive since $v - p^*$ is strictly increasing, $\theta_0 \in (\theta, \min \{p^*, \bar{\theta}\})$, and $\int_{\theta_0}^{p^*} [v(\theta) - p^*] dF(\theta) = w(p^*) = 0$. This, however, is impossible, since each buyer’s payoff is zero in any conservative equilibrium by Proposition 9. The result follows. ■
